This kind of robots has evolved tremendously since the earlier systems developed in the eighties: *Ohio state university (OSU) hexapod* and the *OSU adaptive suspension vehicle (ASV)*, among others. Current legged robots range from those with six legs, *X-RHEX Lite*, with a planar symmetry and three identical legs on each side of the body, or the *multi-appendage robotic system (MARS)*, with its legs distributed along the vertices of a regular hexagon, to four-legged robots with an architecture similar to that of mammals, like *Big Dog* and *Cheetah*. Special mention deserve bipeds, of which the best known are humanoids, with the architecture of the human body, namely, *ASIMO* (advanced step in innovative mobility) and its competitor, *QRIO* (quest for curiosity). Design issues vary, depending on the number of legs. Hexapods offer a combination of static stability and maneuverability, which their four-legged counterparts do not. By far, humanoids are the highest

demanding in terms of static and dynamic stability, but offer the highest mobility.

Hybrid Robots

Hybrid robots stem from the combination of the two foregoing types, wheeled with legged. These are systems that look like wheeled robots, but that feature wheels instead of feet. They offer the advantages – and the disadvantages – of the two foregoing types. A recent example of this kind of robots is NASA's *ATHLETE* (all-terrain hex-legged extra-terrestrial explorer) robot, that features six articulated legs stemming from the edges of a regular hexagon defining the robot body and ending in wheels. Its design is intended for service to the planned Lunar base. According to NASA, the 15-ton lunar habitat would be [16.67]

mounted on top of the six-legged robot. The habitat could walk right off of the lunar lander, and then proceed to any desired location. Wheeled locomotion would be used for level ground; more challenging terrain could be negotiated with the full use of the flexible legs.

16.5.3 Aquatic Robots

Aquatic robots are currently being marketed for operation on water, whether on the surface or underneath. An example of a surface robot is the *Mantra*, intended to act as a lifeguard and help swimmers in distress. Some aquatic robots have been designed with the morphology of fish [16.68]. One swimming robot designed with a hexapod morphology, featuring six flippers in lieu of legs is *Aqua*, developed at McGill University, and depicted in Fig. 16.5.

By far, the aquatic robot with the highest profile is the robotic submarine *Bluefin*, which became a celebrity

Fig. 16.5 Aqua, an amphibious robot

in the search for the debris of Flight MHS370 (Flight went missing on March 7, 2014 at 16:41 GMT.).

16.5.4 Flying Robots

This field is becoming quite active, with some robots mimicking the morphology of insects, and falling into the category of micro-robots [16.69]; other flying robots are designed as unmanned aerial vehicles (UAV) [16.70]. Intensive research is now being reported in the design and control of two novel types of UAVs, namely, drones and quadrotors. The con-

trol of drones undergoing fast maneuvers has been made possible by the inception of gyro-free inertial measurement systems fabricated with microelectromechanical systems (MEMS) technology. Highly maneuverable quadrotors, especially suitable for surveillance and reconnaissance missions, are small-size, light-weight flying machines supplied with *two pairs of counter-rotating rotors and propellers, located at the vertices of a square frame* [16.71]. A recent issue of IEEE's *Robotics & Automation Magazine* [16.72] includes a state-of-the-art account of quadrotor technology.

16.6 Summary

This chapter is devoted to the design of robots, with a focus on serial architectures. In this regard, we started by proposing a stepwise design procedure; then, we recalled the main issues in robot design. These issues pertain to workspace geometry, and to the kinetostatic, the dynamic, the elastostatic and the elastodynamic performances. In doing

this, the mathematics behind the concepts addressed was briefly outlined, so as to make the chapter self-contained.

A major design issue in the design of PKM, namely, stiffness, was given due attention. Design issues pertaining to other kinds of robots, like wheeled, legged, flying and aquatic, were outlined.

17. Limbed Systems

Shuuji Kajita, Christian Ott

A limbed system is a mobile robot with a body, legs and arms. First, its general design process is discussed in Sect. 17.1. Then we consider issues of conceptual design and observe designs of various existing robots in Sect. 17.2. As an example in detail, the design of a humanoid robot HRP-4C is shown in Sect. 17.3. To design a limbed system of good performance, it is important to take into account of actuation and control, like gravity compensation, limit cycle dynamics, template models, and backdrivable actuation. These are discussed in Sect. 17.4.

In Sect. 17.5, we overview divergence of limbed systems. We see odd legged walkers, leg-wheel hybrid robots, leg-arm hybrid robots, tethered walking robots, and wall-climbing robots. To compare limbed systems of different configurations, we can use performance indices such as the gait sensitivity norm, the Froude number, and the specific resistance, etc., which are introduced in Sect. 17.6.

In this chapter, we refer a limbed system as a mobile robot which consists of a body, legs and arms. Its general concept is illustrated in Fig. 17.1.

Let us define that a limbed system must have a body and at least one leg (lower limb) to support and to propel itself. A leg interacts with the environment by its end effector (foot). It can also have an arbitrary number of

arms (upper limb) to manipulate target objects by their end effectors (hands).

From a body-centered point of view, legs can be regarded as special arms designed for manipulating the earth. This justifies us to treat both of the legs and the arms as limbs in a unified manner, thus we chose the word *limbed systems* as the title of this chapter.

17.1 Design of Limbed Systems

General robot design process has already been discussed in the previous 16, therefore, we will concentrate on the specific issues on limbed systems. A design process of actual limbed system can be seen in literatures [17.1–3]. A typical development process may takes the following steps:

- **Step 1: Basic requirements.** A designer must specify the class of tasks performed by the limbed system and its requirements, target velocity, payload, expected environment, etc.
- **Step 2: Conceptual design.** The number of legs and arms, their topology, and associated gait are de-

Fig. 17.1 General concept of a limbed system

cided simultaneously. They must be designed at the same time, because the leg structure and gait are tightly coupled, thus they should not be considered separately. Geometric dimensions of links are also determined based on the basic requirements.

- **Step 3: Detailed design.** A designer selects actuators, sensors, reduction gears, and other mechanical/electrical components to realize the conceptual design. Then the structural elements are designed to integrate the devices.
- **Step 4: Evaluation.** Evaluate the design by building a prototype model or performing computer simulations. In our experience, the first design can never meet the basic requirement, and we are forced to return to Step 3 to change the motor type or the reduction ratio. Sometimes, the simulation results suggest us reconsidering the conceptual design or even rethinking the basic requirements.

Figure 17.2 overviews the development process of a limbed system. Note that a development of a limbed system is an extremely dynamic process, rather than a static top-down development. The detail of each step will be discussed in the following subsections.

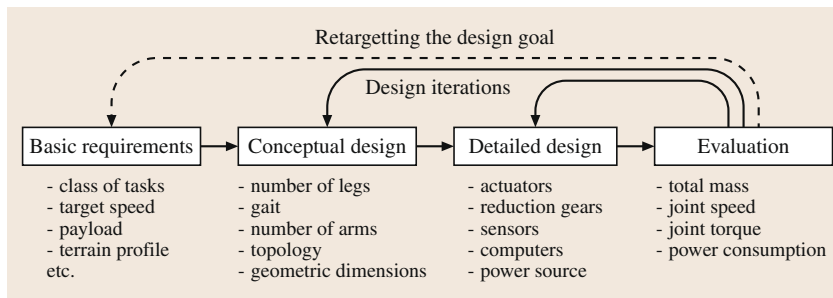

Fig. 17.2 Typical development process of a limbed system

17.2 Conceptual Design

At the beginning, a designer must have a *class of tasks* in his mind, for example:

- Enter a damaged nuclear power plant, climb stairs, and close specified valves
- Explore a planet to seek a new lifeforms
- Carry a person and climb stairs
- Perform dances to entertain its audience, etc..

Note that it must be a class of tasks and should not be a single task, because the latter can be realized by a single degree-of-freedom machinery as expressed in the former chapter.

A class of tasks should be compiled into more specific goals. For example, target speed of traveling, maximum step length, maximum payload, or expected terrain profiles (ex. maximum height of obstacles).

Those figures give a solid guide line for a design process.

17.2.1 Conceptual Design Issues

The goal of conceptual design is to decide the basic kinematic property of the robot, the number of legs and arms, limb topology, and geometric dimensions of the links. A robot designer should take into account the following issues:

- **Gait type:** Leg motion pattern for walking or running is called *gait* and it greatly affects limbed system design. For example, a robot for static gait should be designed to have sprawled posture to maximize its stability. Whereas, a robot for dynamic gait is designed to have erect posture with high center of mass to get a longer time constant of its falling. The gait generation is discussed in 75.
- **Biomimesis:** Some robots are designed to mimic the mechanical structure of a living creature as accurate as possible. This is beneficial for deeper understanding of biological systems. For example, *Quinn* and *Ritzmann* have built a hexapod robot with kinematics that are remarkably similar to the cockroach *Blaberus discoidalis* [17.4] (VIDEO 521). Biomimesis is also meaningful in terms of entertainment applications. *Hirukawa* et al. developed biped walking dinosaur robots of *Tyrannosaurus Rex* and *Parasaurolophus* for an exposition [17.5]. Those robots were built on 30% scale of the real dinosaurs due to safety issues; nevertheless, they could attract many audience by their realistic outlooks at the 2005 World Exposition, Aichi, Japan.
- **Bioinspired dynamics:** To reproduce the robust and versatile locomotion of animals, some designers pay their attention on essential dynamics of the locomotion, rather than the mechanical similarity. *Koditschek* et al. emphasized this standpoint on the development of their hexapod robot RHex, which equipped with only six actuators and yet can run on various irregular terrain [17.6].
- **Mechanical simplicity:** It is preferred to realize the target tasks with a mechanism as simple as possible. Therefore, the design is always biased to use fewer number of actuators. VIDEO 520 shows an example of robot design with minimum numbers of actuators.
- **Limb workspace:** A limb must have at least three degrees of freedom (DOF) to freely locate the tip of a limb in 3-D space. It must have also at least six DOF for the arbitrary orientation of the end effector in 3-D space.

- **Load bearing:** Proper joint assignment can reduce the joint torque to support the body weight. In VIDEO 517, we can see a unique hexapod leg design for efficient load bearing.

17.2.2 Case Studies

Let us observe how abovementioned issues are reflected in the conceptual design of actual limbed systems.

Underactuatedness Versus Redundancy

We compare two monopods which were designed under different policies on actuation. Figure 17.3a is the 3-D one-legged hopping machine developed by *Raibert* [17.1]. This robot is driven by one pneumatic cylinder in its leg and two hydraulic actuators in its hip joints. Therefore, it has only three actuated DOF while 3-D rigid body motion requires 6. Despite its underactuatedness, it can freely travel in 3-D space keeping its body upright thanks to its balance control.

Figure 17.3b shows the one-legged robot developed by *Tajima* and *Suga* [17.7]. It has seven actuated DOFs in total, three at the hip, one at the knee, two at the ankle, and one at the toe. Therefore, this robot is a redundant system having one extra DOF in addition to the six required for 3-D motion. This redundancy can help the robot to reduce the excessive joint speed required at hopping. As a result, successful hopping motion control was realized by using servo motors with reduction gears for all joints.

Serial Versus Parallel

Legs of a limbed system can be configured either as a serial or parallel structures. In most cases, each leg of a biped robot is designed as serial chain of six ac-

Fig.17.3a,b Monopod robot designs. (a) MIT 3-D One-Leg Hopper (1983); (b) Toyota monopod (2006)

uated DOF, where three are used in the hip, one in the knee and two in the ankle. HRP-2 L developed by Kaneko et al. [17.8], as shown in Fig. 17.4a, is one of such examples. For such robots, the most difficult part

Fig.17.4a,b Biped robot designs. (a) HRP-2L (2001); (b) WL-16R (2003)

Fig.17.5a,b Quadruped designs. (a) TITAN III (1984); (b) BigDog (2005)

is the hip joint design. A hip joint mechanism must contain three axis of rotation (roll/pitch/yaw) bearing high torque caused by the upper body weight. This is serious especially for a robot to carry heavy loads.

Takanishi et al. solved this problem by introducing legs of the Stewart platform for their WL-16R, a human carrying biped locomotor (Fig. 17.4b). Each leg consists of six linear actuators driven by DC-gear motors and ball screws. In this design, their robot can carry a human of 50 kg weight [17.9].

Static Gait Versus Dynamic Gait

Figure 17.5a is TITAN III developed by Hirose and his colleagues [17.10]. This is one of the successful quadruped robots in 1980s. Each leg is a 3-D pantograph mechanism driven (PANTOMECH) by three linear actuators (ball screw with DC motor) equipped on its body, thus it has 12 DOF. To perform statically balanced walk, this robot was designed to have a low center of mass and widely spread legs.

Figure 17.5b is BigDog, an energy autonomous hydraulic quadruped robot of 1 m tall, 1 m long, and 90 kg developed by Buehler et al. [17.11]. Each leg has one passive linear pneumatic compliance in the lower leg, three active joints for knee, hip pitch, and roll. There-

Fig.17.6a,b Hexapod designs. (a) ASV (1986); (b) Genghis (1989)

fore it has 12 actuated **DOF** and four passive **DOF**. This robot can demonstrate remarkable walking performance in an outdoor environment, as well as can maintain its balance even when kicked by a human. This ability of dynamic balancing is helped by its design of high center of mass with the leg assignment with narrow lateral separation.

Big Versus Small

Design concept is deeply affected by the robot size. Figure 17.6a shows one of the most famous hexapods, the adaptive suspension vehicle (**ASV**) developed by *Waldron et al.* [17.2, 12]. The **ASV** is a hydraulically driven hexapod robot which can carry a person over rough terrain. Its length and height are 5.2 m and 3.0 m, respectively, and weighs 2700 kg. To walk around in **3-D** space, each leg requires 3 **DOF**s, thus the robot has 18 **DOF** in total.

Figure 17.6b shows a small hexapod robot *Genghis* (35 cm length and 1 kg weight) developed by *Brooks* [17.13]. This robot could also demonstrate robust walking in **3-D** space, but its weight is less than a thousandth of the **ASV**. As a result, *Genghis* does not need precise **3-D** foot positioning for its walking control. Each leg has only two **DOF** and the robot has 12 **DOF** in total. Standing with three legs, the body position and orientation can be fully controlled as long as the feet is allowed to slip on the ground.

Degree of Biomimesis

We can increase the degree of biomimesis by adding **DOF**; however, fewer **DOF** is preferable in terms of en-

Fig.17.7a,b Humanoid designs. (a) ASIMO (2000); (b) HRP-4C (2009)

gineering. The first version of ASIMO has 26 **DOF** in total, 6 for each leg, 5 for each arm, one for each hand, and two for the head (Fig. 17.7a) [17.14]. As a biped walking humanoid robot, this is a reasonable configuration.

Cybernetic human HRP-4C (Fig. 17.7b) was designed to be as close as a human in consideration of applications in entertainment industry [17.15, 16]. It has 44 **DOF** in total, 7 for each leg, 6 for each arm, 2 for each hand and, three for its waist, 3 for its neck, and 8 for its face. Its design detail is discussed in the next section.

17.3 Whole Design Process Example

In this section, we explain the design process of a humanoid robot HRP-4C. We do this to give the readers an example of the whole development process of a limbed system. The readers are also recommended to see the comprehensive development report for the humanoid robot LOLA written by *Lohmeier* [17.3]. Also please watch another successful humanoid designs in [VIDEO 522](#) and [VIDEO 526](#). Note that a general mechanical design and construction process have already been discussed in this handbook (Chap. 4).

17.3.1 Conceptual Design of HRP-4C

At the beginning of our project, we defined *Cybernetic human* as a humanoid robot with the following features:

1. Have the appearance and shape of a human being.
2. Can walk and move like a human being.
3. Can interact with humans using speech recognition and so forth.

Such robots can be used in the entertainment industry, for example, exhibitions and fashion shows. It can also be used as a human simulator to evaluate devices for humans.

As the successor of our previous humanoid robots HRP-2 and HRP-3 [17.17, 18], we call our new humanoid robot HRP-4C, C stands for cybernetic human.

To determine the target shape and dimensions of HRP-4C, we used the anthropometric database for Japanese population, which was measured and compiled by *Kouchi et al.* [17.19]. The database provides

the dimensions of different Japanese groups of ages and sex. Considering the entertainment applications like fashion show, we picked the average young female data (age from 19 to 29). Figure 17.8 shows part of the dimensions provided by the database.

To reproduce women's graceful motion, we asked a professional walking model to perform walking, turning, sitting on chair, and other motions. The performance was motion-captured and used to evaluate possible joint configurations proposed for HRP-4C structure. From the captured data, the required joint workspace was estimated. In addition, we estimated the motor power during biped walking to design the appropriate leg joint configuration.

Figure 17.9 shows the joint configuration we finally decided for HRP-4C. To reproduce the human motion, three DOFs (roll, pitch, yaw) were assigned for each of the waist and the neck joints. In addition, we put active toe joints to realize biped walking with wide stride.

17.3.2 Mechanical Design

Figure 17.10 shows the mechanism to drive the knees of HRP-4C. The rotation of the servo motor is trans-

mitted to the input of the harmonic drive gear by way of the pulleys and the timing belt, and the output of the harmonic gear is connected to the lower leg link. By this way, we can obtain high torque output without backlash which is required for dynamic biped walking. Note that

Fig. 17.8 Anthropometric data of average young Japanese female (after [17.19], all measures in mm)

Fig. 17.9 Joint configuration of HRP-4C body (joints for the face and hands are omitted)

Fig. 17.10 Joint drive system (after [17.8])

the pulleys and the timing belt offer us a flexible choice of the motor placement as well as the total reduction ratio. The belt compliance becomes negligible thanks to the high reduction ratio of the harmonic gear at the final stage.

The same mechanisms of Fig. 17.10 are used for most of the joints of HRP-4C; however, there are some exceptions. The first example is the ankle joint. Figure 17.11 illustrates the mechanism of the left lower leg link and the ankle. The ankle pitch and roll joints are driven by two servomotors (Motor #1 and Motor #2) embedded in the shin link. Motor #1 rotates the ball screw to create the linear motion via timing belt and pulleys. Then the ball screw's nut pushes or pulls the connecting rod that finally drives the ankle pitch joint.

Motor #2's rotation is transmitted to the bevel gear #1, timing belt #2, and the second bevel gear. The bevel gear #2 rotates the harmonic drive gear and it finally rotates the ankle roll joint. This elegant yet complicated mechanism was necessary to realize the slim outer shape of the HRP-4C ankle which must have close dimensions of human ankle.

Figure 17.12 is the toe joint mechanism of HRP-4C. To avoid sole plate separation which may catch obstacles between the plates, the toe joint axis should locate as close as possible to the floor surface. For this purpose, a four bar linkage is used to drive the toe sole plate by the harmonic drive gear mounted on the heel sole plate.

As already mentioned, harmonic drive gears are mainly used because they are backlash free. On the other hand, for the mechanical parts, which do not require backlash-less motion, we can use alternative devices. For this reason, servo motors with planetary gear heads were used as the actuators for facial expressions and hands.

Figure 17.13 is the final mechanical design of HRP-4C (Fig. 17.13a) and its exterior (Fig. 17.13b). The covers for the arms, legs and body are made of fiber reinforced plastics (FRP) and the facial skin and hand skin are made of silicone rubber.

17.3.3 Electrical System Design

Figure 17.14 shows the electronics architecture of HRP-4C. The entire system is controlled by a single board computer of the PCI-104 form factor with Intel Pentium M 1.6GHz. Two peripheral boards, the 10ch controller area network CAN interface board and the force sensor interface board are stacked on the CPU board.

To realize a human-like slender outlook, we used compact motor drivers which were developed in our previous project [17.18]. This device is an intelligent

Fig. 17.11 Ankle joint drive mechanism of HRP-4C

Fig. 17.12 Toe joint mechanism

driver for a single servo motor, which takes an incremental encoder signal and provides motor current by proportional-integral-derivative (PID) control. The driver is small enough to be embedded in leg/arm links nearby the target motor. Since it has a CAN interface which allows cascade connection from the CAN interface board, the wiring can be simplified and reduced.

In addition, we used another CAN-interfaced intelligent drivers for small motors for the face and the hands. This driver can drive multiple motors by handling each incremental encoder, PID feedback, and the current control. We developed this type of

Fig.17.13a,b Mechanism of (a) HRP-4C and its (b) exterior

Table 17.1 Principal specifications of HRP-4C

Height	1,600 mm
Weight	48 kg (with batteries)
Total DOF	44 DOF

	Body: Inertial measurement unit (IMU)
	Sole: 6-axis force sensor × 2
Batteries	NiMH 48 V

driver by modifying the device for our multifingered hand [17.20].

By using these motor drivers and the CAN interface board, we can control 44 servo motors in total. Furthermore, a commercial inertial measurement unit (IMU) is connected via CAN to measure and control of the body posture during biped walk.

The feet of HRP-4C are equipped with six-axis force sensors to measure the zero-moment point (ZMP) for its balance control. These sensor signals are interfaced by the force sensor interface board.

Table 17.1 shows the principal dimensions and specification of the final design of HRP-4C. It becomes

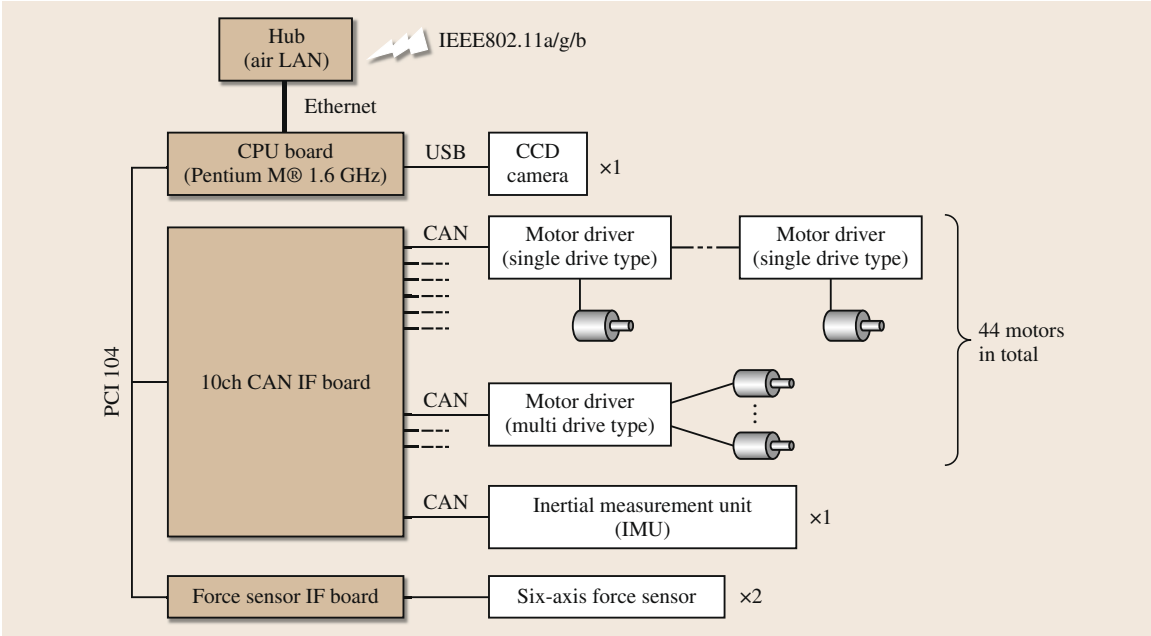

Fig. 17.14 Electronics architecture of HRP-4C

a humanoid robot with 1.6 m height, 46 kg weight, and 44 actuated DOF. The on-board nickel metal hydride battery (NiMH) provides power for 20 min operation time without an external cable. HRP-4C's human-like

walking demonstration and a quick slip-turn experiment are shown in VIDEO 522 and VIDEO 525, respectively.

17.4 Model Induced Design

The design of multilimbed robotic systems is a mechatronic challenge involving expertise in diverse fields such as mechanical design, electrical design, communication and control, as well as software engineering. A task-oriented perspective on the overall system allows in some cases to incorporate a desired function directly into the system design rather than enforcing this behavior by active control. This idea can be found in many robotic designs. The most prominent example might be the use of counterweights for passive gravity compensation employed in robot manipulators. A clever mechanical design thus leads to a smaller power consumption of the actuators and consequently leads to a simplified system design. Passive gravity balancing has been realized via several approaches involving counterweights, springs (Fig. 17.15), and parallel mechanisms [17.21]. Such a gravity compensation based on springs is for example employed in the robot PR2 from Willow Garage (Fig. 17.16) [17.22, 23]. In this section, we will highlight several examples of legged robots where a desired function or property of the final system is realized at least partly via clever mechanical design.

17.4.1 Dynamic Walking

Passive Dynamic Walking

The concept of passive dynamic walking was pioneered by McGeer (VIDEO 527). In the seminal paper [17.24], a class of purely passive mechanical

Fig. 17.15 Passive gravity compensation by a spring: For $Kab = Mgl$ the torques around the hinge produced by gravity and by the spring counter-balance each other

Fig. 17.16 PR2 robot from Willow Garage using springs for passive gravity compensation (after [17.22, 23])

at the time of touch-down of the swing leg, which determines the state variables after the impact based on the state variables before the impact. Often, a perfectly inelastic impact is assumed.

In a fully passive mechanism with given dynamics parameters, the motion is completely determined by the initial condition of the system. The mapping from the initial state to the state at the beginning of the next step is called *stride function* or *return map*. A periodic gait can be characterized by a fixed point of the stride function, and the search for a periodic gait can accordingly be formulated as an optimization problem on the stride function. In general, optimization may involve the initial condition as well as the dynamics parameters including the inclination of the slope.

In order to analyze the stability properties of a periodic gait, McGeer proposed to interpret the stride function as a Poincaré map of the system. Local (orbital) stability can then be decided based on the linearization of the Poincaré map. Since computing the Poincaré map (i. e., computing the stride function) involves solving the open loop dynamics of the system until the next touch-down, this often can only be implemented numerically.

Figure 17.18 shows technical realizations of planar passive dynamic walkers. The walker shown in Fig. 17.18a from Technical University of Delft has the simplest possible configuration with straight legs and point-feet. Premature impact of the swing leg with the ground is avoided by a stepping pattern on the inclined slope. The mechanism in Fig. 17.18b was built at Cornell University based on ideas from McGeer's seminal paper. The arc shape of the foot implements a rolling motion during stance. The ground clearance of the swing leg was realized by a passive knee joint.

Fig. 17.17 Conceptual model of a simple passive dynamic walker

Figure 17.19 shows a fully passive walking machine in 3-D [17.27] (VIDEO 532). It employs soft heels for improving the contact transition. The swinging motion of the arms allows for reducing the angular momentum around the vertical axis as well as side-to-side rocking. Knee extension is limited to a straight configuration by a locking mechanism.

Semipassive Limit Cycle Walker

Purely passive dynamic walkers can produce a stable limit cycle when walking down a shallow slope. Thereby, the energy loss at each impact is compensated

Fig. 17.18a,b Examples of planar passive dynamic walkers with (a) point feet, (b) arc feet, and knees

by the energy gain from the decent along the slope, i. e., these systems are *powered* by gravity.

Several attempts have been made for increasing the versatility and robustness of limit cycle walkers by adding active power sources. Figure 17.20 shows some successful designs reported in [17.28]. In these systems, simple actuation is used for substituting gravitational power in order to allow for walking on level ground. While these systems are not fully passive, their energy consumption is much less than compared to fully actuated walking robots. The Cornell biped, as shown in Fig. 17.20a, utilizes actuation only in the ankle. The actuation is used such that each ankle joint extends when the opposite foot hits the ground. The Delft biped, as shown in Fig. 17.20b, instead is powered at the hip and utilizes passive ankles.

The superior energy efficiency which can be achieved by dynamic limit cycle walkers has been demonstrated in the Cornell Ranger [17.29] that succeeded to walk over a distance of 65 km without recharging or direct human intervention except for the remotely controlled steering.

Fig. 17.19 A 3-D passive walker with upper body (after [17.27])

Actuated Limit Cycle Walkers

Passive and semipassive limit cycle walkers strongly rely on the passive dynamics for realizing a specific gait. In actuated limit cycle walkers the control of some joints is used for imposing a limit cycle on the remaining dynamics. The systems shown in Fig. 17.21 are fully actuated, except for some unactuated degrees of freedom, e.g., at the foot-ground contact, and/or under-actuation due to elasticity.

In the framework of the *hybrid zero dynamics* [17.32], a cyclic variable like the virtual leg angle (angle from the hip to the stance foot) is introduced and the active degrees of freedom are controlled via partial feedback linearization to implement a virtual constraint which describes how the active degrees of freedom are coupled to the cyclic variable. The shape of the virtual constraint is then optimized aiming at a stable limit cycle for the remaining two-dimensional (2-D) zero dynamics. A comprehensive treatment of this approach can be found in [17.33]. Such control approaches were implemented on the robots RABBIT [17.34] and MABLE [17.35]. While RABBIT employed position control in the active degrees of freedom, MABLE was implemented with series elastic actuators allowing for torque-based control (VIDEO 533).

The design of the 3-D walking machine Flame in Fig. 17.21c was also motivated by the aim of combining limit cycle walking with active control [17.36]. The actuation of this robot was also based on series elastic

Fig.17.20a,b Underactuated biped robots: (a) 3-D passive walker (Cornell Biped, 2003) developed at Cornell Univ. (after [17.30]); (b) Denise (2004) (after [17.31])

Fig. 17.21a–c Actuated limit cycle walkers (a) RABBIT (2002); (b) MA-BEL (2008); (c) Flame (2007)

actuation and it was controlled by an event-based state machine in combination with active foot placement for gait stabilization.

17.4.2 Template Models

Conceptual models play an important role as templates for the design and control of legged walking machines. Template models can also be used for generating hypotheses about the neuro-mechanical control in biological systems [17.37]. In this context, they provide a possible answer to Bernstein's **DOF** problem, how the redundancy lying in the human neuro-muscular system is coordinated. We will discuss two conceptual models which have proven useful for legged locomotion.

The linear inverted pendulum (**LIP**) model has been proposed as a template model for bipedal walking (VIDEO 512). Figure 17.22a shows the main forces acting on the center of mass (**COM**) of a legged robot. If all the mass is concentrated in one single point, which implies mass-less legs, the acceleration forces of the

COM are counter balanced by the ground interaction force F acting at the **ZMP** p . If the **COM** is kept at a constant height, i. e., $\ddot{z} = 0$, one immediately obtains the dynamical equations of the linear inverted pendulum model

$$\ddot{x} = \frac{g}{z}(x - p). \quad (17.1)$$

This model has been the starting point for many successful methods aiming at trajectory generation and feedback control of bipedal humanoid robots [17.41–43]. More details on the related control issues can be found in 48. By using this model, the implicit assumption is made that the change of angular momentum around the **COM**, e.g., due to the swing leg dynamics,

Fig. 17.22 (a) The linear inverted pendulum model (after [17.38]) (b) Definition of the centroidal moment pivot (after [17.39, 40])

Fig. 17.23a,b Bipedal robots (a) LOLA (2009); (b) HUBO (2005)

can be neglected. This assumption plays an important role also for the mechanical design. The bipedal robot LOLA (Fig. 17.23a) developed at Technical University of Munich (TUM) is optimized for low inertia in the legs by moving the knee and ankle actuators into thigh [17.44]. In the robot HUBO from KAIST (Fig. 17.23b) the design aimed at concentrating the main inertia into the torso while keeping the mass of the moving parts in the arms and legs small [17.45].

Aiming at a better representation of the change of angular momentum the centroidal moment pivot (CMP) (Fig. 17.22b) was proposed as an additional ground reference point [17.39, 40]. For the more general model in Fig. 17.22b the force balance results in

$$\ddot{x} = \frac{g + \ddot{z}}{z}(x - p) + \frac{\tau}{mz} . \quad (17.2)$$

The CMP is defined as the hypothetical location of the ZMP for the case $\tau = 0$, such that the distance between the ZMP and the CMP is proportional to the change of angular momentum, i. e.,

$$c = p - \frac{\tau}{F_z} , \quad (17.3)$$

where $F_z = m(g + \ddot{z})$. In undisturbed human walking it was observed that the distance between ZMP and CMP is kept small [17.40], while the change of angular momentum plays a stronger role for push recovery [17.46].

An alternative way of modeling the effect of the limb motion (e.g., swing foot dynamics) on the overall dynamics is to consider a three-mass model, which has been utilized in the control of LOLA [17.44] and the Honda humanoid robot ASIMO [17.47].

While the LIP model has been introduced as a conceptual model for walking, it cannot describe running motions in which a flight phase is present. In biomechanics, the spring-loaded inverted pendulum (SLIP) model (Fig. 17.24) was introduced in which the leg is modeled as a linear spring [17.48].

During the stance phase, the dynamics is given by

$$m\ddot{r} = mg + k \left(\frac{l_0}{|r - r_F|} - 1 \right) (r - r_F) , \quad (17.4)$$

Fig. 17.24 The spring loaded inverted pendulum (SLIP) model

where l_0 and k are the rest length and stiffness of the spring, respectively, and r_F is the location of the stance foot. During the flight phase, one simply has $\ddot{r} = g$, and it is assumed that the leg angle instantaneously adjusts to an angle α for preparing the next touch-down. The model contains no damping and impact phenomena are eliminated by assuming mass-less legs. Therefore,

Fig.17.25a,b Hopping robots developed in the MIT LegLab (a) 3-D Biped (1989); (b) Quadruped (1984) (after [17.1])

this model is conservative. It allows to generate periodic hopping trajectories representing running motions. Moreover, the contact force profile resulting from these motions shows similarity to data from human running motions. An extension of the SLIP dynamics to bipedal walking including double support phases was analyzed in [17.49].

The SLIP model can be considered as the simplest model of one-legged hopping and bipedal running. Its compliant leg function can be of interest for the design and control of future legged robots, which aim at highly dynamic motions like fast running, hopping, and jumping.

Gait generation and control of compliant hopping robots have been studied in the 1980s by Raibert in the MIT LegLab. A detailed treatment of these developments is summarized in [17.1]. The basic idea of Raibert's dynamic locomotion approach can be explained by considering a planar one-legged hopping robot. It can be shown that this system can be controlled in a surprisingly simple way by the combination of three separate components:

1. Altitude control which is implemented by a fixed thrust during stance.
2. Control of the forward velocity by placing the foot at a fixed distance from the hip at touch-down.
3. Control of the body attitude during stance using actuation at the hip.

The same principle was applied to a one-legged hopper in 3-D, as well as to bipedal and quadrupedal hopping robots (Fig. 17.25). In the quadrupedal case, the combined effect of alternating pairs of legs was summarized by considering a single virtual leg.

17.4.3 Robots for Control Based on Backdrivable Actuation

A large number of algorithms for model-based control of robotic systems assume a rigid-body model of the robot in which the joint torques act as the control input. The capability of controlling the torque in practice is heavily influenced by the properties of the actuator transmission. While direct drive actuation allows a precise feed-forward control of the actuator torque via the motor current, this leads to rather heavy drive units. The WAM arm from Barrett Technologies (Fig. 17.26a) utilizes direct drive actuation in combination with cable transmissions in order to store the leading four drives into the base of the robot. In this way, a large inertia of the moving elements is avoided. The use of gears with high transmission ratios allows to reduce the overall weight, but leads to slower drive units which are hardly or not at all backdrivable. Joint torque sensing and serial elastic actuation present two hardware-oriented approaches for improving the torque controllability of highly geared actuators.

Joint torque sensing assumes a dedicated sensor for measuring the link side torque τ and was applied in a series of lightweight robot arms de-

Fig.17.29a–c Bipedal robots using serial elastic actuators: (a) Spring Flamingo (1996) (after [17.50]); (b) M2V2 (2008) (after [17.51]); (c) COMAN (2011) developed at IIT utilizing SEA in selected joints (hip, knee, ankle)

veloped at DLR, including the light-weight robot in Fig. 17.26b [17.52] and the upper body robot Justin as shown in Fig. 17.28a [17.53]. Recently, the same drive technology has been integrated in the design of the torque-controlled humanoid robot TORO (Fig. 17.27a) [17.54] (VIDEO 531). Torque sensing and control have also been employed in the hydraulic humanoid CB developed by Sarcos (Fig. 17.27b).

In series elastic actuators (SEAs), the joint torque sensing is implemented indirectly by measuring the deflection of an elastic element which is introduced into the drive train [17.55]. Early robots with compliant actuators were the two armed systems COG [17.56] from MIT and Wendy [17.57] from Waseda university, which even allowed the adaptation of the compliance. More recently, series elastic actuators are used in the compliant arm A2 from Mekka (Fig. 17.26c) and the humanoid upper body robot Twenty-one from Waseda university (Fig. 17.28). They have been also applied to bipedal systems in the robots as shown in Fig. 17.29 (also watch VIDEO 529 and VIDEO 530).

While the mathematical models of torque controlled robots and robots with SEA have the same structure it should be mentioned that the source of elasticity is

different in these approaches. In SEA, the deflective element for the torque sensing represents the main source of elasticity and its role is to decouple the motor and link side dynamics for high frequency disturbances like impacts. A well-designed torque sensor instead should not introduce a big effect on the overall joint stiffness (in this case usually the gear introduces the main source of elasticity). Despite their conceptual similarity, the literature of SEA and elastic joint robots also differs in the way that in the context of SEA usually the linear dynamics of a single compliant actuator is considered for the controller design, while in the context of elastic joint robots the full nonlinear multibody dynamics is considered.

From a modeling and control point of view, the use of torque sensors in the joints leads to a robot model with elastic joints. For actuators with a high transmission ratio, a common modeling assumption is that the kinetic energy of each rotor depends only on its own spinning motion and not on the rigid body motion of the other joints [17.58]. Let the motor and link side joint angles be denoted by $\theta \in \mathbb{R}^n$ and $q \in \mathbb{R}^n$, then the *reduced flexible joint model* (Chap 11 for a detailed derivation) is given by

$$\mathbf{M}(q)\ddot{q} + \mathbf{C}(q, \dot{q})\dot{q} + \mathbf{g}(q) = \boldsymbol{\tau} + \boldsymbol{\tau}_{f,q}, \quad (17.5)$$

$$\mathbf{B}\ddot{\theta} + \boldsymbol{\tau} = \boldsymbol{\tau}_m + \boldsymbol{\tau}_{f,\theta}, \quad (17.6)$$

Fig. 17.30 Conceptual model of an elastic joint: A proportional feedback of the joint torque reduces the effective motor inertia and motor friction

where $\mathbf{M}(q)$, $\mathbf{C}(q, \dot{q})\dot{q}$, and $\mathbf{g}(q)$ represent the link side inertia matrix, the centrifugal and Coriolis forces, and the gravity term of the rigid body dynamics. The motor inertia is given by the diagonal matrix \mathbf{B} . The vector $\boldsymbol{\tau}$ represents the joint torques. In the case of an elastic joint with linear joint stiffness k_i the torque is given by $\tau_i = k_i(\theta_i - q_i)$. The terms $\tau_{f,q}$ and $\tau_{f,\theta}$ represent the effective friction terms at the link side and the motor side, respectively.

Fig. 17.31 The torque sensing based joint technology of DLR's light weight robot arm

A purely proportional feedback of the joint torques

$$\tau_m = -(\mathbf{K}_\tau - I)\tau + \mathbf{K}_\tau u \quad (17.7)$$

has the effect that the motor dynamics equation (17.6) shows a controlled behavior as

$$\mathbf{K}_\tau^{-1} \mathbf{B} \ddot{\theta} + \tau = u + \mathbf{K}_\tau^{-1} \tau_{f,\theta} . \quad (17.8)$$

Let us assume that \mathbf{K}_τ is chosen as a diagonal matrix. Then we see that the matrix $\mathbf{K}_\tau^{-1} \mathbf{B}$ corresponds to an effective (i. e., virtual) motor inertia matrix. By choosing the gains in \mathbf{K}_τ larger than unity, we can thus reduce the effective motor inertia (Fig. 17.30). Moreover also the effects of motor friction are reduced such that a torque controlled joint ultimately exhibits a backdrivable behavior even if the underlying gear mechanism is not or only hardly backdrivable.

From this interpretation of torque feedback, we can derive some general guidelines for the mechanical

design of torque-controlled robots. Since the effective motor side friction can be reduced by a simple proportional torque feedback but link side friction is not affected, we conclude that the mechanical design should aim at low friction at the link side and the torque sensing should be implemented at the power output side of the gear. Since the assembly of gear and torque sensor is assumed to behave like an ideal spring, any masses of moving parts in the transmission should be kept low in order to minimize unmodeled dynamics which would affect the validity of (17.7). As an example of a successful design, Fig. 17.31 shows a cross-section of a joint of the torque-controlled DLR-light-weight-robot-III [17.52] in which a harmonic drive transmission is combined with a strain gauge-based torque sensor.

Instead of the simple proportional control of (17.7), a complete torque controller can be designed based on the torque dynamics

$$\mathbf{B} \mathbf{K}^{-1} \ddot{\tau} + \tau = \tau_m + \tau_{f,\theta} + \mathbf{B} \ddot{q} , \quad (17.9)$$

resulting from (17.6) and $\tau = K(\theta - q)$. Torque tracking is achieved via

$$\tau_m = \tau_d + \mathbf{B} \mathbf{K}^{-1} \ddot{\tau}_d + \tau_{f,\theta} + K_q \mathbf{B} \ddot{q} + u(\tau_d - \tau) , \quad (17.10)$$

where $u(\tau_d - \tau)$ represents a proportional-derivative (PD) or PID control law and the nonnegative factor $K_q < 1$ is chosen less than 1 in order to avoid an overcompensation of the link side acceleration. In the context of SEA such a controller was proposed based on a linear system representation of a single joint in [17.55]. Cascaded torque control of a single SEA-based joint using an inner loop velocity controller has been analyzed in [17.59, 60], also using a linear model. In the context of torque-controlled elastic joint robots, in [17.61] a combination with a Cartesian impedance controller was proven to be stable for the full nonlinear dynamics based on the stability theory of cascaded systems (using $K_q = 1$). Passivity-based control has been analyzed in [17.62].

17.5 Various Limbed Systems

In this section, we explore the divergence of the limbed system design.

17.5.1 Odd Legged Walkers

A robot can be designed by pure engineering. For example, the tripodal walking robots STriDER (self-

excited tripodal dynamic experimental robot) 1 and 2 (Fig. 17.32) can demonstrate a unique locomotion which have never developed by evolution [17.63] and  VIDEO 534. It has three identical legs each of them has four DOF, three at the hip and one at the knee. Supporting the body with two legs, the robot takes a dynamic step by swinging the rest leg. Since the body flips

Fig. 17.32 STriDER 1 and 2

with 180° about the aligned pelvis joints connecting the support legs, the robot can continue its dynamic walk.

Five legged walkers have been developed by some groups. For example, *Besari et al.* developed a five-legged robot inspired from starfish, and applied reinforcement learning to obtain its optimal gait [17.64].

17.5.2 Leg-Wheel Hybrid Robots

Unlike animals or insects, a robot can be designed to have wheels which can rotate infinitely. By mixing the efficiency of wheels and the flexibility of legs, we

can expect a robot of maximum terrain adaptivity with minimum power consumption. Figure 17.33 shows examples of such a design concept.

Figure 17.33a shows a stair climbing of a biped leg-wheeled robot developed by *Matsumoto et al.* [17.65]. The robot is a planer biped with telescopic legs, but the tip of each leg is equipped with a powered wheel. During a single leg support phase, the robot is controlled as a wheeled inverted pendulum. In addition, a controller was developed to realize the smooth transient between single support and statically stable double support phase.

Figure 17.33b is RollerWalker developed by *Hirose et al.* [17.66, 69]. RollerWalker is a 12 DOF quadruped robot equipped with passive wheels on the tip of legs. It uses roller-skating mode on a flat floor, while it can walk on an uneven terrain by retracting the passive wheels (VIDEO 535).

Figure 17.33c is RHex developed by *Buehler, Koditchev et al.* [17.67]. Although it was originally inspired from the locomotion of cockroach, RHex has only six active DOF, that is, one actuator for each hip. Moreover, the legs can rotate full circle around the pitch axis. By this unique design, RHex can walk and run over rugged, broken, and obstacle-ridden ground (VIDEO 536). Recently, it also demonstrated biped running with its rear legs [17.70].

Figure 17.33d is Whigs II, another cockroach-inspired robot developed by *Allen et al.* [17.68]. This robot has only 4 active DOFs, one for propulsion, two for steering and one for body flexion. Each leg is equipped with three spring-loaded spoke and driven by

Fig.17.33a–d Leg-wheel hybrid robots. (a) Biped leg–wheel robot (1998); (b) Roller walker (1996); (c) RHex (2001); (d) Whigs II (2003) (after [17.65–68])

Fig.17.34a,b Leg-arm hybrid robots (a) MELMANTIS-1 (1996); (b) Yanbo3 (2003) (after [17.72, 73]) ◀

the same actuator (▶ VIDEO 537). Whegs II can realize comparable mobility to RHEx, while it uses fewer actuators.

17.5.3 Leg-Arm Hybrid Robots

Another design concept is a leg-arm hybrid robot. Since legs have inherently many degree of freedom, it is possible to use them as manipulators. By this way, we can minimize total DOF, complexity, weight and power consumption of the walking robot. MELMANTIS-1 (Fig. 17.34a) developed by *Koyachi* et al. is a hexapod walker of 22 DOF, which can transform its legs into manipulators [17.72]. The robot can manipulate an object by two legs while standing with four other legs, after traveling by six legs with the maximum stability.

Yanbo3 is a biped walker of 8 DOF developed by the group of *Ota* et al. [17.73]. It is designed to have minimum DOF necessary for a biped robot as well as for a manipulator when it is in the single support. In Fig. 17.34b, the robot is pressing the elevator button by its foot.

17.5.4 Tethered Walking Robots

Figure 17.35 shows Dante II, an eight-legged tethered walking robot developed by CMU Field Robotics Center in 1994. It was used at an Alaskan volcano for scientific exploration. To descend down steep crater walls in a rappelling-like manner, the robot uses tether cable anchored at the crater rim [17.71]. *Hirose* et al. also developed tethered quadruped for construction work [17.74].

Fig. 17.35 Dante II (1994) (after [17.71])

17.5.5 Wall-Climbing Robots

Wall-climbing robots are characterized by their foot mechanisms and leg configurations. The vital part is the foot mechanism to generate pulling force and the use of vacuum suction cups, electromagnets (for steel wall), adhesive materials, or miniature spine array has been proposed.

Figure 17.36a shows a wall-climbing quadruped NINJA-1 developed by *Hirose* et al. [17.75] Each foot of NINJA-1 is equipped with a specially designed suction pad which can minimize its vacuum leakage. Another reliable wall-climbing robot with suction cups was developed by *Yano* et al. [17.76]

Fig.17.36a,b Wall-climbing robots. (a) NINJA-1 (1991); (b) RiSE (2005) (after [17.75, 77]) ◀

Figure 17.36b shows a wall-climbing hexapod RiSE developed by Kim et al. [17.77, 78]. Each foot of RiSE is equipped with arrays of miniature spines observed in some insects and spiders. The robot can reliably climb

on a wide variety of outdoor surfaces including concrete, stucco, brick, and dressed sandstone. As a wall-climbing robot more recently developed, watch Stickybot III in [VIDEO 540](#) and Waalbot in [VIDEO 541](#).

17.6 Performance Indices

In this section, we introduce useful performance indices, that can be used to evaluate legged robots of different configurations.

17.6.1 Stability Margins

The stability margin was originally proposed for a degree of stability of the statically walking multilegged robots by McGhee and Frank [17.79]. By neglecting the inertial effects caused by body and leg acceleration, we can guarantee the robot keep balance if the projection of center of mass (COM) exists inside the support polygon as shown in Fig. 17.37. (Note: In multilegged robot research, the word *support pattern* is frequently used for support polygon [17.2, 79, 80].)

For a given configuration of a walking robot, the *stability margin* S_m is defined as the minimum distance of the vertical projection of COM to the boundaries of the support pattern in the horizontal plane as illustrated in Fig. 17.38a.

In addition, an alternative index was proposed to obtain the optimal gait analytically. That is the *longitudinal stability margin* S_l which is defined as the minimum distance from the vertical projection of COM to the support pattern boundaries along the line parallel to the body motion.

For a dynamic walking robot, we can define a stability margin as the minimum distance of the ZMP to the boundaries of the support polygon, since ZMP is the natural extension of a projected COM on the ground.

Fig. 17.37 Support polygon (support pattern) of multi-legged robot

This fact has already been mentioned in the original work of ZMP [17.81], and has been implicitly used by many researchers. Explicit definition of this *ZMP stability margin* can be seen, for example, in Huang et al. [17.82].

For a legged robot on a rough terrain, Messuri and Klein defined the *energy stability margin* as the minimum potential energy required to tumble the robot as,

$$S_E = \min_i (Mgh_i), \quad (17.11)$$

where h_i is the COM height variation during the tumble around the i -th segment of the support polygon and M is the total mass of the robot [17.83]. This concept is widely accepted, and there are some proposals for improvement [17.14, 84].

17.6.2 Gait Sensitivity Norm

Hobbelen and Wisse proposed a gait sensitivity norm (GSN) as a disturbance rejection measure of limit cycle walking machines [17.85]. GSN is defined as

$$\text{GSN} = \left\| \frac{\partial \mathbf{g}}{\partial \mathbf{e}} \right\|_2, \quad (17.12)$$

where \mathbf{e} is the set of disturbances and \mathbf{g} is the gait indicator which characterizes the *failure mode*, motion finally end up a tumble. For a 2-D limit cycle walker, they took floor irregularities (step height to walk over) and step time as \mathbf{e} and \mathbf{g} , respectively.

For real robots, GSN can be experimentally obtained from the response of gait indicators \mathbf{g} to a single

Fig. 17.38a,b Definition of stability margins. (a) Stability margin; (b) Longitudinal stability margin

disturbance e_0 as

$$\left\| \frac{\partial \mathbf{g}}{\partial \mathbf{e}} \right\|_2 = \frac{1}{|e_0|} \sqrt{\sum_{i=1}^q \sum_{k=0}^{\infty} [\mathbf{g}_k(i) - \mathbf{g}^*(i)]^2}, \quad (17.13)$$

where $\mathbf{g}_k(i)$ is the i -th gait indicator value at k steps after the disturbance e_0 has applied, q is the number of gait indicators. GSN has a good correlation with the basin of attraction, hence it can be used for a design of a robust walking robot and its controller.

17.6.3 Duty Factor and Froude Number

Throughout this chapter, we have observed various walking robots which might fit best for certain environment and purpose. In some cases, however, we need to compare walking robots which have different masses, sizes, and leg numbers by using a certain performance index. Such an index should be dimensionless like a Mach number or a Raynolds number in fluid mechanics.

One of the useful indices for walking machines is a duty factor β defined as

$$\beta = \frac{(\text{support period})}{(\text{cycle time})}.$$

Duty factors can be used to make the distinction between walks and runs, since we have $\beta \geq 0.5$ for walking and $\beta < 0.5$ for running [17.87].

Froude number is used in fluid mechanics to explain the behavior of surface waves. Since both of surface waves and legged locomotion are dynamic motion in gravity, *Alexander* used it to characterize animal locomotion [17.87, 88]. He calculated a Froude number by

$$Fr_2 = \frac{V^2}{gh}, \quad (17.14)$$

where V is the walking or running speed, g is the gravity acceleration, and h is the height of hip joint from the ground. He showed animals of different sizes uses similar gaits when they travel with equal Froude numbers. Especially, most animals changes

Fig. 17.39 Gabielli-von Karman diagram (after [17.86])

their gait from walking to running at the speed of $Fr_2 = 1$.

Froude number is also defined as

$$Fr_1 = \frac{V}{\sqrt{gh}}, \quad (17.15)$$

which is the square root of Fr_2 and can be used non dimensional speed of animals or legged robots.

17.6.4 Specific Resistance

The *specific resistance* is another important dimensionless number, which is used to evaluate the energy efficiency of a mobile robot.

Gabrielli and von Karman discussed the performance of various vehicles using the power consumption per unit distance. That is

$$\epsilon = \frac{E}{Mgd}, \quad (17.16)$$

where E is the total energy consumption for a travel of distance d , M is the total mass of the vehicle and g is gravity acceleration [17.89]. Note that when we push a box of mass M for a distance d on a floor with a friction coefficient μ , we consume the power $Mg\mu d$ and the specific resistance becomes $\epsilon = \mu$. Therefore, we can say that the specific resistance indicates how smooth the locomotion is.

In the original work, Gabrielli and von Karman plotted the specific resistance as the function of speed for various vehicles (Fig. 17.39). This is called the *Gabrielli-von Karman diagram* and it was used to compare various styles of locomotion by *Umetani* and *Hirose* [17.90]. *Gregorio* et al. also showed the specific resistance of recent walking robots including their efficient hopping robot, ARL monopod [17.86]. *Collins* et al. developed robots based on passive-dynamics with small actuators and achieved energy efficiency close to human walking [17.91]. In the paper, the specific resistance is referred to as *specific energetic cost of transport*.

18. Parallel Mechanisms

Jean-Pierre Merlet, Clément Gosselin, Tian Huang

This chapter presents an introduction to the kinematics and dynamics of parallel mechanisms, also referred to as parallel robots. As opposed to classical serial manipulators, the kinematic architecture of parallel robots includes *closed-loop kinematic chains*. As a consequence, their analysis differs considerably from that of their serial counterparts. This chapter aims at presenting the fundamental formulations and techniques used in their analysis.

18.1 Definitions

A *closed-loop kinematic chain* is one in which the links and joints are arranged such that at least one closed loop exists. Furthermore, a *complex closed-loop kinematic chain* is obtained when one of the links – other than the base – has a degree of connectivity greater than or equal to 3, i. e., one link other than the base is connected through joints to at least three other links. A *parallel manipulator* can be defined as a closed-loop mechanism composed of an end effector having n degrees of freedom (DOF) and a fixed base, linked together by at least two independent kinematic chains.

An example of such a structure was patented in 1928 by Gwinnett [18.1] to be used as a platform for a movie theatre. In 1947, Gough [18.2] established the basic principles of a mechanism with a closed-loop

kinematic structure (Fig. 18.1) that allows the positioning and the orientation of a moving platform so as to test tire wear and tear. He built a prototype of this machine in 1955.

For this mechanism, the moving effector is a hexagonal platform whose vertices are all connected to a link by a ball-and-socket (spherical) joint. The other end of the link is attached to the base by a universal joint. A linear actuator allows the modification of the total length of the link; this mechanism is, therefore, a closed-loop kinematic structure, actuated by six linear actuators.

In 1965, Stewart [18.3] suggested the use of such a structure for flight simulators and the Gough mechanism is sometimes referred to as the *Stewart platform*

Fig. 18.1 Gough platform

Fig. 18.2 The Delta robot

or the *Gough–Stewart platform*. The same architecture was also concurrently proposed by *Kappel* as a motion simulation mechanism [18.4]. Nowadays, the Gough platform and its variants are the platform of choice for many applications, for example, flight simulators. This application provides a convincing illustration of the main advantage of parallel robots namely, their load-carrying capacity. Indeed, while the ratio of the mass of the payload over the mass of the robot is typically smaller than 0.15 for serial 6R industrial robots, this ratio can be larger than 10 for parallel structures. Another advantage of the Gough platform is its very good positioning accuracy (although it has been questioned [18.5]). This high accuracy arises from the fact that the legs work essentially in tension/compression and are subjected to virtually no bending – thereby

Fig. 18.3 The 3- \underline{RPR} planar parallel robot

leading to very small deformations – and from the fact that the errors in the internal sensors of the robot (measurement of the lengths of the legs for the Gough platform) are mapped into very small errors of the platform position. Parallel robots are also almost insensitive to scaling (the same structure can be used for large or micro robots) and they can be built using almost any type of joint, actuator, or transmission, including exotic ones such as tape spring and flexure joints [18.6] or binary actuators [18.7]. The main drawbacks of parallel robots are their small workspace and the singularities that can appear within this workspace. However, large workspaces may be obtained using wire transmissions (see, for example, the Robocrane [18.8]): such robots will be specifically addressed in Sect. 18.10 as their analysis is somewhat different. Apart from the Gough platform, the most successful designs of parallel robots are the Delta robot proposed by *Clavel* [18.9] (Fig. 18.2) and some planar parallel robots. The most common planar parallel robots have three identical legs each having an \underline{RPR} or \underline{RRR} architecture, where the underlined joint is the actuated one (such robots are often denoted as 3- \underline{RPR} (3- \underline{RRR} ; Fig. 18.3).

The geometric arrangement of the joints and links of the Delta structure provides three translational degrees of freedom at the platform. Numerous other types of parallel robots have been proposed in the recent years. Although most existing architectures are based on the intuition of their designer, the synthesis of parallel mechanisms can be dealt with systematically. An overview of the main approaches to the type synthesis of parallel mechanisms is given in the next section.

18.2 Type Synthesis of Parallel Mechanisms

Determining all potential mechanical architectures of parallel robots that can produce a given motion pattern at the moving platform is a challenging problem. Several authors have addressed this problem, referred to as type synthesis. The approaches proposed in the literature can be divided into four groups:

- *Approaches based on graph theory:* The enumeration of all possible structures having a given number of DOFs can be performed by considering that there is only a finite set of possible kinematic pairs, and hence a very large, but finite, set of possible structure combinations (e.g., [18.10]). Classical mobility formulae – for example, the Chebychev–Grübler–Kutzbach formula – are then used to determine the number of DOFs in the structure. Unfortunately, these formulas do not take into account geometric properties of the mechanism that can change the number of DOFs of the platform. Although many parallel robots have been successfully invented and developed for industrial uses, based on graph theory – the Neos Tricept [18.11] and the Sprint Z3 head of DS Technologie GmbH, for example – the synthesis approaches based strictly on graph theory can produce only limited nonoverconstrained parallel robots and have been largely superseded by the other methods described below.
- *Approaches based on group theory:* The motion of a rigid body has the special structure of a group, the *displacement group*. Subgroups of the group of displacements, such as the spatial translations or all the translational and rotational motions about all axes that are parallel to the axis defined by a given vector (Schönflies motion [18.12]), play an important role as they can be combined through the *intersection* operation [18.13] when elements of subgroups act on the same rigid body. Type synthesis consists in determining all the possible subgroups to which the different kinematic chains that will constitute the legs of the robot may belong to so that their intersection leads to the desired motion pattern for the platform. The synthesis approaches based on group theory led to the discovery of numerous possible architectures [18.14]. Nevertheless, the displacement group has special properties that are not reflected by its group structure alone. Also, the approach is limited to motion patterns that can be described by a subgroup of the displacement group.
- *Approach based on differential geometry:* As a full extension and completion of the Lie-group-algebraic method, the differential geometry method

can be used to cover the motion patterns that cannot be modeled by subgroups but regular submanifolds, a plane-hinged parallelogram, for example [18.15]. The additional merit of the geometric method lies in that it enables to link the finite motion with the instantaneous motion of the platform thanks to the integral/differential relationship between the Lie group and Lie algebra.

- *Approaches based on screw theory:* In this approach, the first step is to determine the wrench system S that is reciprocal to the theoretically accessible instantaneous twist (or velocity twist) of the moving platform. Then, the wrenches of each limb whose union spans the system S (and that determine all the possible structures of the kinematic chains that will generate the corresponding wrenches) are enumerated. Although this method is very effective at providing simple and intuitive descriptions of the instantaneous motions of the platform, it is necessary to verify that the mobility of the platform is full cycle and not only instantaneous as all considered twists and wrenches are instantaneous. Thus, techniques to ensure the consistency between the finite and instantaneous motions have also been developed. A systematic implementation of this approach is provided in [18.16].

The above synthesis methods have been used to generate a large number of architectures that cannot be presented in this book, but the website [18.17] presents a comprehensive description of a large number of mechanical architectures. Among others, several remarkable architectures were proposed in the recent years to generate Schönflies motions using the innovative concept of articulated plates, leading to a brand new pick-and-place parallel robot known as Adept Quattro [18.18]. Also, other similar architectures allowing unlimited rotations of the end effector while avoiding all singularities have recently been proposed (see for instance [18.19]).

It should also be pointed out that although these synthesis methods can be used to generate a large number of architectures [18.20], there is a lack of a metric to evaluate which one is better than the other even if they have completely identical motion patterns. Furthermore, it is hard to link the models for type synthesis with those for kinematic, static, and dynamic analyses and design. Open issues, therefore, include:

- To develop suitable performance metrics for each motion type to identify suitable topological structures for specific applications.

- To develop a complete theoretical package that enables type synthesis and parametric design to be integrated into a unified framework that takes

into account the unavoidable uncertainties in the manufacturing process, an ultimate objective of design.

18.3 Kinematics

18.3.1 Inverse Kinematics

The solution of the inverse kinematic problem is usually straightforward for parallel robots. This can be illustrated with the Gough platform.

The solution of the inverse kinematic problem consists in determining the vector of leg lengths \mathbf{q} for a given pose of the platform defined by the position vector \mathbf{p} of a given point on the platform in a fixed reference frame and a rotation matrix \mathbf{R} representing the orientation of the platform with respect to the fixed frame. Let \mathbf{a}_i denote the position vector of the anchor point of the i -th leg on the base given in the fixed reference frame and \mathbf{b}_i denote the position vector of the anchor point of the i -th leg on the platform, given in a moving frame attached to the platform. The length of the i -th leg is the norm of the vector connecting the two anchor points. This vector, noted \mathbf{s}_i , can be written as

$$\mathbf{s}_i = \mathbf{p} + \mathbf{R}\mathbf{b}_i - \mathbf{a}_i, \quad i = 1, \dots, 6. \quad (18.1)$$

Given the pose of the platform (vector \mathbf{p} and matrix \mathbf{R}), vector \mathbf{s}_i is readily calculated using (18.1) and, hence, the leg lengths can be obtained.

18.3.2 Forward Kinematics

The solution of the forward kinematic problem consists in determining the pose of the platform for a given set of actuated joint coordinates (a given vector \mathbf{q}). This solution is needed for control purposes, calibration, and motion planning.

The forward kinematic problem of a parallel robot is usually much more complex than the inverse kinematic problem. Indeed, the loop closure equations (18.1) are typically highly nonlinear expressions of the pose variables. They form a nonlinear set of equations that generally admits multiple solutions (e.g., the Gough platform can have up to 40 solutions [18.21–23], while a table with the number of solutions for Gough platforms with special geometries is provided in [18.24]). The forward kinematic problem arises in two different contexts. In the first case, no estimate of the current pose of the platform is available (e.g., when starting the robot), while in the second case, a relatively precise estimate of the pose is known (e.g., in real-time con-

trol when the forward kinematics has been solved at the previous sampling time of the controller). In the first case, the only known approach is to determine all the solutions of the inverse kinematic equations, although there is no known algorithm to sort the set of solutions. It is often possible to determine an upper bound on the number of real solutions. Consider, for example, the case of the planar 3-RPR robot (Fig. 18.3). If the joint at point B_3 is disassembled, two separate mechanisms are obtained, namely, a 4-bar linkage and a rotary lever. From the kinematics of 4-bar linkages, it is known that point B_3 moves on a sixth-order algebraic curve. Moreover, it is also known that point B_3 of the lever moves on a circle, that is, a second-order algebraic curve. For a given set of actuated joint coordinates, solutions to the forward kinematic problem arise when the two curves intersect, that is, when the mechanism can be assembled. Bezout's theorem states that algebraic curves of order m , n intersect in nm points, counting their order of multiplicity. In the above case, this means that the curves intersect in 12 points. However, these 12 points include the two circular imaginary points that belong to the coupler curve of the 4-bar linkage and to any circle, thereby to their intersection. These points are counted three times in Bezout's theorem and, hence, the forward kinematic problem will have at most six real solutions, corresponding to the intersection points.

Various methods have been proposed for the solution of the forward kinematic problem: elimination [18.25], continuation [18.23], Gröbner bases [18.26], and interval analysis [18.27]. Elimination is usually not very stable numerically (i.e., it can produce spurious roots and miss solutions) unless special care is taken in the implementation of the resulting univariate equation and the elimination steps. For instance, the transformation of polynomial solutions into eigenvalue problems can be used [18.28]. Polynomial continuation, on the other hand, is much more stable numerically since mature algorithms can be found in the literature [18.29]. The fastest methods – although not appropriate for a real-time use – are Gröbner bases and interval analysis. They also have the advantage of being numerically certified (no roots can be missed and the solution can be computed with an arbitrarily prescribed accuracy).

However, in the simplest cases, elimination can usually be used to produce stable implementations as, for example, for the 3- RPR robot [18.30, 31]. Finally, it is pointed out that the forward kinematic problem solved for one type of robot may often be used for another architecture: for example, the one developed above for the 3- RPR robot may be used for the 3- RRR . This is typical for parallel robots.

When a priori information (an initial guess of the solution) is available, the forward kinematics is usually solved using the Newton–Raphson or the Newton–Gauss iterative scheme. Consider the solution to the inverse kinematic problem, written as

$$\mathbf{q} = \mathbf{f}(\mathbf{x}) . \quad (18.2)$$

Iteration k of the Newton–Raphson procedure is written as

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{A}(\mathbf{q} - \mathbf{f}(\mathbf{x}_k)) , \quad (18.3)$$

where \mathbf{q} is the vector of prescribed joint variables. Matrix \mathbf{A} is usually chosen as $(\partial \mathbf{f} / \partial \mathbf{q})^{-1}(\mathbf{x}_k)$ (the inverse matrix may not be computed at each iteration or even be chosen as constant). The iterative scheme stops when the magnitude of the difference vector $(\mathbf{q} - \mathbf{f}(\mathbf{x}_k))$ is smaller than a chosen threshold.

Provided that a good initial estimate of the solution is available, the Newton–Raphson algorithm is usually very fast. However, the procedure may not converge or, even worse, it may converge to a solution that is not the correct pose of the platform, that is, it may converge to another assembly mode. Such a situation can occur even if the initial guess is arbitrarily close to the correct pose. If the result is used in a control loop, the consequences can be catastrophic. Fortunately, mathematical tools, such as the Kantorovitch theorem combined with interval analysis can be used to determine if the solution

found by the Newton–Raphson scheme is the correct pose of the robot, that is, to certify the result at the cost of a longer computation time, yet still compatible with real time [18.27].

Furthermore, the choice of the inverse kinematics equations plays an important role in the convergence of this method [18.27]. For example, for a Gough platform, a minimal set of equations (six equations involving six unknowns: three for the translation and three orientation angles) can be used but other representations are possible. For instance, the position coordinates of three of the platform anchor points – in the fixed reference frame – can be used as unknowns (the coordinates of the remaining three points are then readily computed upon convergence). Using this representation, nine equations are needed. Six equations are obtained based on the known distances between the anchor points on the base and platform and three additional equations are obtained based on the known distances between all combinations of the three selected platform anchor points.

Another possible approach for the solution of the forward kinematic problem is either to add sensors on the passive joints (e.g., on the U joints of a Gough platform) or to add passive legs with sensed joints. The main issue is then to determine the number and location of the additional sensors that lead to a unique solution [18.32–34] and to determine the effect of the sensor errors on the positioning error of the platform. For example, Stoughton mentions that for a Gough platform with sensors in the U joints, it is still necessary to use the Newton–Raphson scheme to improve the accuracy of the solution because the solutions obtained with the additional sensors are very sensitive to measurement noise [18.35].

18.4 Velocity and Accuracy Analysis

Similarly to serial robots, the actuated joint velocity vector of parallel robots $\dot{\mathbf{q}}$ is related linearly to the vector of translational and angular velocities of the platform (for simplicity, the latter vector is denoted here as $\dot{\mathbf{p}}$ although the angular velocity is not the time derivative of any set of angular parameters). The linear mapping between the two vectors is provided by the Jacobian matrix \mathbf{J}

$$\dot{\mathbf{p}} = \mathbf{J}(\mathbf{p})\dot{\mathbf{q}} . \quad (18.4)$$

However, for parallel robots, a closed-form expression is usually available for the inverse Jacobian \mathbf{J}^{-1} but this

is much more difficult for \mathbf{J} (more precisely, the closed-form for most 6-DOF robots will be so complex that it cannot be used in practice). For example, a simple static analysis can be used to show that the i -th row \mathbf{J}_i^{-1} of matrix \mathbf{J}^{-1} for a Gough platform can be written as

$$\mathbf{J}_i^{-1} = (\mathbf{n}_i \quad \mathbf{c}_i \times \mathbf{n}_i) , \quad (18.5)$$

where \mathbf{n}_i represents the unit vector defined along leg i and \mathbf{c}_i is the vector connecting the origin of the mobile frame attached to the platform to the i -th anchor point on the platform.

The effect of the joint sensor errors $\Delta \mathbf{q}$ on the positioning error $\Delta \mathbf{p}$ follows the same relationship, namely

$$\Delta \mathbf{p} = \mathbf{J}(\mathbf{p}) \Delta \mathbf{q}. \quad (18.6)$$

Since matrix \mathbf{J} is difficult to be obtained in a closed form, accuracy analysis (i.e., finding the maximal positioning errors over a given workspace for bounded joint sensor errors) is much more difficult than for serial robots [18.36, 37]. Apart from the measurement errors, there are other sources of inaccuracy in parallel robots, namely, clearance in the passive joints, manufacturing tolerances, thermal errors, gravity induced and dynamic errors [18.38, 39]. The effect of joint clearances on trajectories followed by serial and parallel robots was studied in [18.40–42]. According to these works, it is impossible to determine trends for the effect of the geometric errors: a case-by-case study must be performed since the effect is highly dependent on the mechanical architecture, dimensioning, and workspace of the robot. Thermal effects are sometimes mentioned as possible sources of inaccuracy, although few works substantiate this claim [18.43] and cooling may slightly reduce their effects [18.44, 45].

Calibration is another means of improving the accuracy of parallel robots. This issue was addressed in Chap. 3. The methods and procedures used for parallel robots differ slightly from the ones used for serial robots since only the inverse kinematic equations are available and the positioning of the platform is much less sensitive to the geometric errors than in serial robots [18.46, 47]. Hence, the measurement noise occurring during calibration has a significant impact and may lead to surprising results. For example, the classical least-squares method may lead to parameters that are such that some constraint equations are not satisfied even when the measurement noise is taken into account [18.48] or even to parameter values that are unrealistic. It has also been shown with experimental data that classical parallel robot modeling leads to constraint equations that do not have any solution irrespective of the measurement noise [18.49]. Moreover, calibration is very sensitive to the choice of the calibration poses [18.50]: it seems that the optimal choice is to select poses on the workspace boundary [18.51, 52]. We may also mention an original calibration approach based not on the proprioceptive sensors of the robot but on leg observation with a vision system [18.53].

18.5 Singularity Analysis

The analysis of singularities of parallel mechanisms was first addressed in [18.54]. In this formulation, the kinematic equations were reduced to the input–output relationship between the actuated joint coordinate vector \mathbf{q} and the platform Cartesian coordinate vector \mathbf{p} , namely,

$$f(\mathbf{q}, \mathbf{p}) = 0. \quad (18.7)$$

Differentiating (18.7) with respect to time leads to

$$\mathbf{B}\dot{\mathbf{q}} + \mathbf{A}\dot{\mathbf{p}} = \mathbf{0}. \quad (18.8)$$

Three types of singularities can then be defined: *i*) when matrix \mathbf{B} is singular (termed serial singularity), *ii*) when matrix \mathbf{A} is singular (termed parallel singularity) and *iii*) when the input–output equations degenerate (termed architecture singularity) in which case both matrices \mathbf{A} and \mathbf{B} can be singular. In a serial singular configuration, the joints can have a nonzero velocity, while the platform is at rest. In a parallel singularity, there exist nonzero platform velocities for which the joint velocities are zero. In the neighborhood of such a configuration, the robot can undergo an infinitesimal motion, while the actuators are locked. Since the mobility of the end effector should be zero when the actuators

are locked, it is also said that in such a configuration, the robot *gains* some DOFs. As a consequence, certain degrees of freedom of the platform cannot be controlled, and this is a major problem.

A more general study of singularities was proposed by Zlatanov *et al.* [18.55]. The latter analysis uses the velocity equations involving the full twist of the end effector and all joint velocities (passive or actuated). This approach led to a more detailed classification of singularities and was also used later to reveal special singularities (referred to as *constraint singularities*) [18.56] that could not be found with the analysis presented in [18.54]. Also, the singularity analysis of parallel mechanisms was revisited more recently in [18.57], where hierarchical levels in which different critical phenomena originate are recognized.

The singularity analyses discussed above are of the first order. Second- (and higher-) order singularity analyses can also be performed, although these analyses are much more complex [18.42, 58].

18.5.1 Parallel Singularity Analysis

This type of singularity is especially important for parallel robots because it corresponds to configurations in

which the control of the robot is lost. Furthermore, very large joint forces can occur in the vicinity of singular poses that may lead to a breakdown of the robot. The main issues to be addressed in this context are:

1. The characterization of the singularities.
2. The definition of performance indices representing the closeness to a singularity.
3. The development of algorithms that are capable of detecting the presence of singularities over a given workspace or trajectory.

Parallel singularities arise when the 6×6 full inverse Jacobian \mathbf{J}_f (i.e., the matrix that maps the full twist of the platform into active – and eventually passive – joint velocities) is singular, that is, when its determinant $\det(\mathbf{J}_f)$ is equal to 0. It is pointed out that passive joint velocities sometimes have to be included because restricting the analysis to the active joint velocities may not allow the determination of all singular configurations of the mechanism (see the example of the 3-*UPU* robot [18.59]). Usually, a proper velocity analysis allows one to establish this matrix in a closed form. But computing the determinant of this matrix may be difficult even with symbolic computation tools (see the example of the Gough platform [18.60, 61]) and it does not provide an insight into the geometric conditions associated with the singularities.

An alternative approach is to use line geometry: indeed, for several parallel robots (although not all), a row of \mathbf{J}_f corresponds to the Plücker vector of some line defined on the links of the robot. For example, for a Gough platform, the rows of \mathbf{J}_f are the normalized Plücker vectors of the lines associated with the legs of the robot. A singularity of matrix \mathbf{J}_f , therefore, implies a linear dependency between these vectors (they then constitute a *linear complex*), a situation that may occur only if the lines associated with the vectors verify particular geometric constraints [18.62]. These geometric constraints have been identified by Grassmann for every set of 3, 4, 5, or 6 vectors. Singularity analysis is, thus, reduced to determining conditions on the pose parameters for which these constraints are satisfied, giving geometric information on the singularity variety. A variant of this approach is to use the Grassmann Cayley algebra that in certain cases may lead directly to the geometric singularity conditions [18.63].

Measuring closeness between a pose and a singular configuration is a difficult problem: there exists no mathematical metric defining the distance between a prescribed pose and a given singular pose. Hence,

a certain level of arbitrariness must be accepted in the definition of the *distance* to a singularity and none of the proposed indices is perfect. For example, a possible index is the determinant of \mathbf{J}_f : unfortunately, when the platform is subjected to both translational and rotational motion, the Jacobian matrix is not dimensionally homogeneous and, hence, the value of the determinant changes according to the physical units used to describe the geometry of the robot. Dexterity indices, as defined in Chap. 10 (although they are much less relevant for parallel robots than for serial robots [18.37]), can also be used, and special indices for parallel robots have also been proposed [18.64–66]. For example, it may be interesting for a Gough platform to define a workspace as singularity-free if for any pose the absolute value of the joint forces is lower than a given threshold [18.67] or to use a physically meaningful index like the kinematic sensitivity [18.68].

Most of the analyses based on the above indices are local, that is, valid only for a given pose, while in practice the problem is to determine if a singular configuration can occur over a given workspace or trajectory. Fortunately, an algorithm exists that allows this verification, even if the geometric model of the robot is uncertain [18.69]. However, it should be pointed out that a singularity-free workspace may not always be optimal for parallel robots. Indeed, other performance requirements may impose the presence of singularities in the workspace or the robot may have part of its workspace singularity-free (for example its working region) while exhibiting singularities outside this region. Therefore, a motion planner producing a trajectory that avoids singularities while remaining close to a desired path is advisable and various approaches have been proposed to address this problem [18.70, 71]. A related problem is to determine if two solutions of the forward kinematics may be joined without crossing a singularity: this has been proved for planar robots [18.72, 73] but also for 6-DOF robots [18.74].

Finally, it is noted that being close to a singular configuration may be useful in some cases. For example, large amplification factors between the end-effector motion and the actuated joint motion may be interesting for fine positioning devices with a very small workspace or for improving the sensitivity along some measurement directions for a parallel robot used as a force sensor [18.75]. It should also be mentioned that parallel robots that remain *permanently* in a singular configuration may be interesting since they are capable of producing complex motions with only one actuator [18.76–78].

18.6 Workspace Analysis

As mentioned earlier, one of the main drawbacks of parallel robots is their small workspace. Moreover, their workspace analysis is usually more complex than for serial robots, especially if the platform has more than 3-DOFs. Indeed, the platform motion capabilities are usually coupled, thereby prohibiting simple graphical representations of the workspace. *Decoupled robots* have also been proposed [18.79–81] (👁️ VIDEO 54 and 👁️ VIDEO 52), but they do not provide the load-carrying capacity of conventional parallel robots. In general, the workspace of parallel robots is restricted by the following:

- The limitations on the actuated joint variables: for example, the lengths of the legs of a Gough platform have a minimum and maximum value.
- The limitations on the range of motion of the passive joints: for example, the U and S joints of a Gough platform have restricted ranges of angular motion.
- The mechanical interferences between the bodies of the mechanism (legs, base, and platform).

Different types of workspaces can be defined such as, for example, the *dextrous* workspace (the set of platform locations in which all orientations are possible), the *maximal* workspace (the set of platform locations that may be reached with at least one orientation), or the *orientation* workspace (the set of orientations that can be reached for a given location of the platform).

A possible approach for representing the workspace of parallel robots with $n > 3$ DOFs is to fix the value of $n - 3$ pose parameters in order to be able to plot the workspace over the remaining 3-DOFs. Such plots can be obtained very efficiently using geometric methods if the plotted variables involve only translational motions because a geometric approach usually allows one to establish directly the nature of the boundary of the workspace (e.g., [18.82, 83] for the calculation of the workspace of a Gough platform when its orientation is fixed). Another advantage of this approach is that it allows the computation of the surface and volume of the workspace. Possible alternatives include:

- Discretization methods in which all poses of an n -dimensional grid are checked with respect to all types of kinematic constraints. Such methods are usually simple to implement but are computationally intensive because the computation time increases exponentially with the resolution of the mesh. Also, they require a large storage space.
- Numerical methods that allow the determination of the workspace boundary [18.84, 85].

- Numerical methods based on interval analysis that allow the determination of an approximation of the workspace volume up to an arbitrary accuracy [18.86, 87]. This representation is also appropriate for motion planning problems.

Singularities can also split the workspace calculated from the above kinematic constraints into elementary components, called the *aspects* by Wenger and Chablat [18.88] and which are separated by a singularity variety. Some very good results have been obtained for planar robots [18.89] but determining the aspects for spatial robots is still an open problem. A parallel robot may not always be able to move from one aspect to another (at least without considering the dynamics of the robot [18.90, 91]) and hence the useful workspace can be reduced.

A problem related to workspace analysis is the *motion planning problem*, which is slightly different from that encountered with serial robots. For parallel robots, the problem is not to avoid obstacles within the workspace but either to determine if a given trajectory lies entirely inside the workspace of the robot and is singularity-free (for which an algorithm is available [18.92]) or to determine such a trajectory between two poses which is much more difficult [18.93]. Indeed, classical serial robot motion planners work in the joint space and assume that there is a one-to-one relationship between the joint space and the operational space. With this assumption, it is possible to determine a set of points in the joint space that is collision-free and to use this knowledge to build a collision-free path between two poses. However, this assumption is not valid for parallel robots because the mapping between the joint space and the operational space is not one to one: a point in the joint space may either correspond to multiple points in the operational space or have no correspondence because the closure equations of the mechanism are not satisfied. For parallel robots, the most efficient motion planner seems to be an adaptation of a probabilistic motion planner that takes into account – to a certain extent – the closure equations [18.94, 95].

Another motion planning problem is related to tasks where a limited number of DOFs of the robot are used, while the others may be used to increase the machine's workspace, to avoid singularities or to optimize some performance index of the robot [18.96, 97]. Along the same line, it is possible to define the *part positioning* problem [18.98] as determining the pose of a rigid body with respect to the workspace of the robot so that this pose satisfies some constraints.

18.7 Static Analysis

Similarly to serial robots, the static analysis of parallel robots can be readily performed using the Jacobian matrix. Indeed, the mapping between the vector of actuated joint forces/torques $\boldsymbol{\tau}$ and the external wrench \mathbf{f} exerted by the platform can be written as

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{f}, \quad (18.9)$$

where \mathbf{J}^T is the transpose of the Jacobian matrix of the robot. Equation (18.9) can be used for various purposes, namely:

- During the *design* process in order to determine the maximal actuator forces/torques over the robot workspace (for actuator selection). This is a complex issue since \mathbf{J}^T is not known in a closed form.
- In applications where the robot is used as a *force sensor*: If $\boldsymbol{\tau}$ is measured and the pose of the platform is known, then (18.9) can be used to calculate \mathbf{f} so that the robot can be used both as a motion and sensing platform [18.99–101].

The stiffness matrix \mathbf{K} of a parallel robot is defined similarly to that of serial robots as

$$\mathbf{K} = \mathbf{J}^{-T} \mathbf{K}_j \mathbf{J}^{-1}, \quad (18.10)$$

where \mathbf{K}_j is the diagonal matrix of actuated joint stiffness. Duffy [18.102] notes that this derivation is, in general, incomplete. For example, for a Gough platform this derivation assumes that there is no initial load on the elastic element of the link. Assuming that the length of the unloaded link is q_i^0 leads to

$$\begin{aligned} \Delta \mathbf{f} &= \sum_{i=1}^{i=6} k \Delta q_i \mathbf{n}_i + k_i (q_i - q_i^0) \Delta \mathbf{n}_i, \\ \Delta \mathbf{m} &= \sum_{i=1}^{i=6} k \Delta q_i \mathbf{c}_i \times \mathbf{n}_i + k_i (q_i - q_i^0) \Delta (\mathbf{c}_i \times \mathbf{n}_i), \end{aligned}$$

where k_i denotes the axial stiffness of the leg, \mathbf{n}_i represents the unit vector defined along the i -th leg, \mathbf{c}_i is the vector connecting the origin of the moving reference frame to the i -th anchor point of the platform, and \mathbf{f}, \mathbf{m} are the external force and moment vectors that are applied by the platform. Consequently, the stiffness matrix as defined in (18.10) is valid only if $q_i = q_i^0$, and is coined the *passive stiffness*.

Moreover, it was pointed out in the literature [18.103] that the formulation of (18.10) is valid

only when the external wrench is zero. Indeed, the above formulation does not account for the fact that the Jacobian matrix is configuration dependent and therefore changes with the applied loads. The formulation proposed in [18.103] and termed *conservative congruence transformation* (CCT) takes these changes into account and leads to a stiffness matrix defined as

$$\mathbf{K}_c = \mathbf{J}^{-T} \mathbf{K}_j \mathbf{J}^{-1} + \left(\frac{\partial \mathbf{J}^{-T} \boldsymbol{\tau}}{\partial \mathbf{p}} \right), \quad (18.11)$$

where \mathbf{p} is the vector of Cartesian coordinates and $\boldsymbol{\tau}$ is the vector of actuated joint forces/torques. Whenever possible, the formulation of (18.11) should be used instead of that of (18.10) because it is mechanically consistent.

Another interesting static problem is the static balancing of parallel robots. The static balancing of mechanisms, in general, has been an important research topic for several decades (e.g., [18.104] for an account of the state of the art and many recent new results). Parallel mechanisms are said to be *statically balanced* when the weight of the links does not produce any torque (or force) at the actuators under static conditions, for any configuration of the manipulator or mechanism. This condition is also referred to as *gravity compensation*. The gravity compensation of parallel mechanisms was addressed in [18.105] where the use of counterweights was suggested to balance a 2-DOF parallel robot used for antenna aiming, and in [18.106] for planar robots. This analysis leads to simple and elegant balancing conditions.

In general, static balancing can be achieved using counterweights and/or springs  VIDEO 48. When springs are used, static balancing can be defined as the set of conditions for which the total potential energy in the mechanism – including gravitational energy and the elastic energy stored in the springs – is constant for any configuration of the mechanism. When no springs – or other means of storing elastic energy – are used, then static balancing conditions imply that the center of mass of the mechanism does not move in the direction of the gravity vector, for any motion of the mechanism.

Sufficient conditions under which a given mechanism is statically balanced may be obtained. The problem of statically balancing spatial parallel robots is usually complex [18.107, 108]). Among other results, it was pointed out that it is not possible to balance a 6-UPS robot in all poses by using only counterweights [18.109] (U stands for a Hooke joint, P stands for a prismatic joint and S stands for a spherical joint). Alternative mechanisms (using parallelograms) that can

be balanced using only springs were suggested [18.107, 110, 111].

A natural extension of static balancing is dynamic balancing. The dynamic balancing problem consists in finding parallel mechanisms that do not produce any reaction force or torque on their base for ar-

bitrary trajectories. This problem was addressed for planar and spatial parallel mechanisms. In [18.112], it was shown that dynamically balanced parallel mechanisms with up to 6-DOFs can be synthesized, although the resulting mechanical architectures may be complex (VIDEO 49).

18.8 Dynamic Analysis

The dynamic model of parallel robots has a form similar to that of serial robots (Chap. 3), namely,

$$\mathbf{M}(\mathbf{x})\ddot{\mathbf{p}} + \mathbf{C}(\dot{\mathbf{p}}, \dot{\mathbf{q}}, \mathbf{p}, \mathbf{q}) + \mathbf{G}(\mathbf{p}, \mathbf{q}) = \boldsymbol{\tau}, \quad (18.12)$$

where \mathbf{M} is the positive-definite generalized inertia matrix, \mathbf{G} is the gravitational term, and \mathbf{C} is the centrifugal and Coriolis term. However, this equation is more difficult to obtain for parallel robots because the closure equations have to be satisfied. A classical method for calculating the dynamic models of closed-chain mechanisms is to consider first an equivalent tree structure, and then to enforce the kinematic constraints using Lagrange multipliers or d'Alembert's principle [18.113, 114]. Other approaches include the use of the principle of virtual work [18.115–118], the Lagrange formalism [18.119–122], Hamilton's principle [18.123], and Newton–Euler equations [18.124–129].

The main drawback of dynamic models obtained for parallel robots is that they are usually rather complex, they require the determination of dynamic parameters that are often not well known (dynamic identification of closed-loop mechanisms being not trivial [18.130]), and they usually involve solving the forward kinematics. Therefore, their calculation is computer intensive while they must be used in real time.

Using dynamic models for control purposes was proposed [18.131, 132], usually in the context of an adaptive control scheme, in which the tracking errors are used on-line to correct the parameters used in the dynamic equations [18.133, 134]. Control laws were proposed mainly for planar robots and for the Delta robot [18.135, 136], although some implementations have been proposed for general 6-DOF robots [18.137, 138] or vibration platforms [18.139]. However for 6-DOF robots, the benefits of using dynamic models for high-speed motions are difficult to establish because the computational burden of the dynamic model somewhat reduces the potential gains. An original approach is to work directly in the joint space, using information obtained on the legs' orientation through a vision system, allowing to get rid of the forward kinematics [18.140].

Dynamic control is an important and open issue since parallel robots can operate at velocities and accelerations much larger than those of serial robots. For example, some of the Delta robots have reached accelerations of the order of 500 m/s² (with an objective of reaching 100 G [18.141]) while wire-driven robots can probably exceed this value.

Finally, the optimization of the dynamic properties of parallel mechanisms can be addressed by minimizing the variation of the inertia over the workspace [18.142].

18.9 Design

The design of a robot can be decomposed into two main phases:

- *Structural synthesis*: Finding the general mechanical structure of the robot.
- *Geometric synthesis*: Determining the value of the geometric parameters involved in a given structure (here geometric parameters has a loose sense: for example, mass, inertia may also be involved).

The problem of structural synthesis (type synthesis) was addressed in Sect. 18.2. However, performance requirements other than the motion pattern of the robot have to be taken into account in the design of a robot.

Serial robots have the advantage that the number of possible mechanical architectures is relatively small and that some of these architectures have clear advantages in terms of performance compared to others (for example the workspace of a 3R structure is much larger than the workspace of a Cartesian robot of similar size).

Unfortunately, no such rules exist for parallel robots, for which there are furthermore a large number of possible mechanical designs. Additionally, the performances of parallel robots are very sensitive to their geometric parameters. For example, the extremal stiffness of a Gough platform over a given workspace can change by 700% for a change of only 10% of the platform radius. Consequently, structural synthesis cannot

be dissociated from the geometric synthesis. In fact, it is conjectured that a well-dimensioned robot of any structural type will, in general, perform better than a poorly designed robot with a structure that may seem more appropriate for the task at hand.

Usually, the design process is treated as an optimization problem. To each specified performance requirement is associated a performance index whose value increases with the level of violation of the performance requirement. These performance indices are summed in a weighted real-value function, called the *cost function*, which is a function of the geometric design parameters, and then a numerical optimization procedure is used to find the parameters that minimize the cost function (hence, this approach leads to what is called an *optimal design*) [18.143–145]. There are, however, numerous drawbacks to this approach: the determination and effect of the weights in the cost function are difficult to ascertain, imperative requirements are difficult to incorporate and complexify the optimization process, and the definition of the performance indices is not trivial, only to name a few. The main issues can be stated as follows:

- It is quite difficult to ensure that the global minima is reached in spite of using relatively new optimization methods such as neural network or genetic algorithm.
- The robustness of the design solution obtained with the cost function approach with respect to the uncertainties in the final design. Indeed, the real instanti-

ation of a theoretical solution always differs from the theoretical solution itself because of the manufacturing tolerances and other uncertainties that are inherent to a mechanical system.

- Performance requirements may be antagonistic (e.g., workspace and accuracy), and the approach only provides a compromise between these requirements that is difficult to master through the weights.

An alternative to optimal design is referred to as *appropriate design*, in which no optimization is considered, but the objective is to ensure that desired requirements are satisfied. This approach is based on the definition of the *parameter space* in which each dimension is associated with a design parameter. Performance requirements are considered in turn and the regions of the parameter space which correspond to robots satisfying the requirements are calculated. The design solution is then obtained as the intersection of the regions obtained for each individual requirement.

In practice, only an approximation of the regions is necessary since values close to the boundary cannot be physically realized due to the manufacturing tolerances. For that calculation, interval analysis was successfully used in various applications [18.36, 146].

The appropriate design approach is clearly more complex to implement than the cost function approach but has the advantage of providing all design solutions, with the consequence that manufacturing tolerances may be taken into account to ensure that the real robot also satisfies the desired requirements.

18.10 Wire-Driven Parallel Robots

Parallel mechanisms naturally lead themselves to another paradigm that exploits the structural properties of wires (cables). Cables are mechanical components that can withstand large tensile loads relative to their weight. When applied to parallel mechanisms, a plurality of cables can be attached to a moving platform and driven by actuated reels mounted on the base frame. Because of the parallel architecture, it is possible to ensure that cables can be maintained under tension within a given workspace. Wire-driven parallel mechanisms have been studied by several researchers over the last 20 years (e.g., [18.8, 147] for early work). The advantages of these mechanisms are numerous. When wound on a spool, cables allow motion ranges that are much larger than that produced by conventional articulated systems. Also, because they can only resist to tensile forces, cables are, as mentioned above, much thinner and lighter than most conventional mechanical components, for similar payloads. Thus, they have

very low inertia and are particularly suitable for systems in which large ranges of motion are required. Indeed, long-reach articulated robots are heavy and involve the motion of significant mass, whereas cable-driven robots remain light even when the range of motion is very large. This property is clearly exemplified by aerial video camera systems such as the SkyCam [18.148] or in  VIDEO 44, which shows an application in the scanning of artifacts for the generation of digital three-dimensional (3-D) models.  VIDEO 45 and  VIDEO 50 show another application in material handling.

Because wires can only resist tensile loads, wire-driven parallel mechanisms are generally designed based on either one of the two following approaches, namely: (1) the weight (gravity) of the moving platform is used to ensure that all cables are under tension or (2) the number of cables is larger than the number of degrees of freedom of the platform, thereby allowing

a pre-stressing of the cables that can be used to ensure that all cables remain under tension. The wire-driven parallel mechanisms that are designed based on the first approach are referred to as *cable-suspended parallel mechanisms*, while the mechanisms that are based on the second approach are referred to as *fully constrained wire-driven parallel mechanisms*.

18.10.1 Cable-Suspended Parallel Mechanisms

Most cable-suspended parallel mechanisms are not redundantly actuated: they typically include as many actuators as DOFs. These mechanisms have been proposed in the literature as potential candidates for applications that require very large workspaces or mechanisms that can provide effective payload to mass ratios. One of the first cable-suspended mechanisms that was built is the Robocrane [18.8], developed by NIST almost two decades ago. This 6-DOF robot was intended for crane-type operations in which the pose of the payload can be fully controlled. Other cable-suspended mechanisms have also been studied and prototypes were built to validate their performance (e.g., [18.149] and [18.150]). More recently, cable-suspended parallel mechanisms including more actuators than DOFs were proposed, and it was shown that their workspace-to-footprint ratio can be much larger than that of nonredundant cable-suspended parallel mechanisms [18.151]. This is convincingly illustrated in  VIDEO 45 and  VIDEO 50, where a cable-suspended parallel mechanism with eight cables is demonstrated.

Most of the cable-suspended parallel mechanisms proposed or built in the past were assumed to work under static or quasi-static conditions. Under this assumption, the workspace can be determined based on the static equilibrium of the moving platform. The workspace is defined as the set of platform poses for which static equilibrium can be obtained while maintaining tension in all cables. Techniques to determine the static workspace of cable-suspended robots were proposed in the literature, for instance, in [18.152]. The dynamic trajectory planning and control of cable-suspended parallel mechanisms were also investigated in the recent literature (e.g., [18.153–156]), leading to cable-suspended parallel mechanisms that can be operated beyond their static workspace. The concept of dynamic workspace then arises [18.157], which can be defined as the set of poses that the platform can reach with at least one kinematic state (position, velocity, and acceleration).

Finally, it should be mentioned that the determination of the static pose of an underactuated cable-suspended parallel mechanism – that is, one with fewer

cables than DOFs – is a very complex problem that has not yet been completely solved [18.158, 159]. In fact, for a given platform and given cable lengths, it is possible that an equilibrium pose can be reached, although some of the cables are not under tension. Therefore, the determination of the static pose involves not only solving for the actual number of cables, n , but also for all subrobots with $n - 1$ cables.

18.10.2 Fully Constrained Wire-Driven Parallel Mechanisms

Fully constrained wire-driven parallel mechanisms have also attracted a great deal of attention. Fully constrained mechanisms include a number of cables larger than the number of degrees of freedom of the mechanism. If a proper geometry is used, they generally exhibit a wrench-closed workspace within which the platform can resist arbitrary external wrenches, while maintaining the cables in tension.

The statics of wire-driven robots can be described by

$$\mathbf{W}\boldsymbol{\tau} = \mathbf{f}, \quad (18.13)$$

where $\boldsymbol{\tau}$ is the vector of tensions in the wires, \mathbf{f} is the wrench at the platform, and \mathbf{W} is the so-called wrench matrix, which is configuration dependent. Since fully constrained wire-driven parallel mechanisms include more cables than DOFs, their wrench matrix \mathbf{W} contains more columns than rows. Based on the above equation, the wrench-closed workspace can then be defined as the set of poses for which there exists at least one vector in the nullspace of \mathbf{W} that has all its components of the same sign. When this condition is satisfied, the mechanism is said to be tensionable [18.160] and can theoretically resist arbitrary external wrenches simply by increasing the pre-stress in the cables.

The determination and the optimization of the wrench-closure workspace is a challenging problem that has attracted significant attention. Although the early work presented in [18.149, 161, 162] was mainly applicable to planar wire-driven robots, it paved the way to more general analyses by providing a mathematical modelling of the problem. Determining whether a given pose of the platform is located within the wrench-closure workspace is a rather straightforward problem. However, discretizing the workspace and applying such a criterion to a mesh of points does not solve the problem satisfactorily because the wrench-closed workspace is generally not convex and may even be composed of disconnected components. Therefore, more powerful techniques are needed in order to obtain reliable and useful results. In [18.163], in-

terval analysis is used to determine the wrench-closed workspace of fully constrained wire-driven parallel robots while providing definite answers.  VIDEO 45 and  VIDEO 50 show an example of fully constrained wire-driven parallel mechanisms.

18.10.3 Design and Prototyping

Synthesizing a wire-driven parallel mechanism for a prescribed wrench-closed workspace is a very challenging issue [18.164]. Also, in addition to the workspace, several other issues must be considered in the design of wire-driven parallel robots, for example, the determination of the potential interferences

between the wires. An elegant geometric solution to this problem is proposed in [18.165] but handling translations and rotations simultaneously remains a challenge. Other design problems include the handling of special configurations and assembly mode changes as well as the accuracy and the practical implementation of the spools [18.166].

Several prototypes of wire-driven parallel robots were built and reported in the literature. Early prototypes include the NIST Robocrane [18.8], the Falcon robot [18.147], and the skycam system [18.148]. Many others were built, including those shown in the videos accompanying this chapter and the potential applications are numerous.

18.11 Application Examples

Parallel robots have been successfully used in many applications, a few of which are now briefly mentioned. Almost all recent land-based telescopes use parallel robots, either as a secondary mirror alignment system (e.g., the University of Arizona MMT or the ESO VISTA) or as a primary mirror pointing device [18.6]. A wire-driven parallel robot flew in the space shuttle mission STS-63 in February 1999 while an octopod (a parallel robot with eight legs) was used to isolate the space shuttle payload from vibration. All flight simulators use a parallel structure as a motion platform. They are nowadays used for driving simulators as well (e.g., the NADS-driving simulator [18.167]). In industry, numerous machine tools based on parallel structures have been designed. Some of them have found a niche market (e.g., the Tricept) and it can be expected that more will be used in the future. Ultra ac-

curate positioning devices based on parallel robots are proposed by companies, such as Physik Instrumente, Alio, Micos, and Symétrie. In the food industry, the Delta robot proposed by ABB and Demareux is widely used for fast packaging. Other companies such as Adept are also developing fast parallel robots with 3- and 4-DOFs. Medical applications are also growing, for example, in rehabilitation (after the pioneering work of the Rutgers ankle [18.168] and the platform Caren of Motek), in surgery (for example for spine surgery with the Renaissance robot of Mazor or for vitreoretinal surgery [18.169]) or for training and monitoring the motion of human joints [18.170], a topic in which cable-driven robots play an important role, as they do for aerial robots [18.171] or rescue operation (a version of the SkyCam robot has been used to fight oil fires during the Iraqi War).

18.12 Conclusion and Further Reading

The analysis of a parallel mechanism may be partly based on methods that are presented in other chapters of this handbook:

- *Kinematics*: Kinematics background is covered in Chap. 2.
- *Dynamics*: General approaches are presented in Chap. 3 while identification of the dynamic parameters is addressed in Chap. 6.
- *Design*: Design methodologies are covered in Chap. 16.
- *Control*: Control issues are presented in Chaps. 7, 8, and 9 although the closed-loop structure of parallel robots may require some adaptation of the control schemes.

It must also be emphasized that efficient numerical analysis is a key point for many algorithms related to parallel robots. A system solving with Gröbner basis, continuation method, and interval analysis is essential for kinematics, workspace, and singularity analysis. Further information and up-to-date extensive references and papers related to parallel robots can be found on the following two websites [18.38, 100]. Useful complementary readings on parallel robots are [18.140, 147, 164]. Parallel robots are slowly finding their way into various applications, not only in industry but also in field and service robotics, as discussed in Part F of this handbook. Still, compared to their serial counterpart, their analysis is far from being complete.

19. Robot Hands

Claudio Melchiorri, Makoto Kaneko

Multifingered robot hands have a potential capability for achieving dexterous manipulation of objects by using rolling and sliding motions. This chapter addresses design, actuation, sensing and control of multifingered robot hands. From the design viewpoint, they have a strong constraint in actuator implementation due to the space limitation in each joint. After briefly introducing the overview of anthropomorphic end-effector and its dexterity in Sect. 19.1, various approaches for actuation are provided with their advantages and disadvantages in Sect. 19.2. The key classification is (1) remote actuation or build-in actuation and (2) the relationship between the number of joints and the number of actuator. In Sect. 19.3, actuators and sensors used for multifingered hands are described. In Sect. 19.4, modeling and control are introduced by considering both dynamic effects and friction. Applications and trends are given in Sect. 19.5. Finally, this chapter is closed with conclusions and further reading.

Human hands have great potentialities not only for grasping objects of various shapes and dimensions, but also for manipulating them in a dexterous manner. It is common experience that, by training, one can perform acrobatic manipulation of stick-shaped objects, manipulate a pencil by using rolling or sliding motions, perform precise operations requiring fine control of small tools or objects. It is obvious that this kind of dexterity cannot be achieved by a simple gripper capable of open/close motion only. A multifingered robot hand can therefore provide a great opportunity for achieving such a dexterous manipulation in a robotic system. Moreover, we have also to consider that human beings do not use hands only for grasping or manipulating objects. Exploration, touch, perception of physical properties

(roughness, temperature, weight, just to mention a few) are other fundamental tasks that we usually are able to perform thanks to our hands. We expect this type of capabilities also from robotic end-effectors and therefore, by adding quite advanced sensing equipments and proper control strategies, we may improve the interaction capabilities with the environment, achieving for example active exploration, detection of sensing surface properties (local friction, impedance, and so on), tasks that are usually very hard or impossible for simple grippers. For these and other reasons the study of multifingered robot hands has strongly interested the research community since the early days of Robotics. It was in late 1970s that Okada developed a multifingered robot hand with a tendon driving system

and demonstrated a nut opening motion [19.1]. In early 1980s, two major projects on multifingered robot hands have been launched: the Stanford/Jet Propulsion Laboratory (JPL;  VIDEO 751) hand and the Utah/Massachusetts Institute of Technology (MIT) hand [19.2, 3]. These two robot hands still represent a milestone and a term of comparison for the design of new devices. Since then, several multifingered hands have been designed and developed in a number research institutes all over the world. Among the most known, one can mention the Deutsches Zentrum für Luft- und Raumfahrt (DLR) hand(s) ( VIDEO 754,  VIDEO 768, and  VIDEO 769), Mechanical Engineering Laboratory (MEL) hand, Electro-Technical

Laboratory (ETL) hand, Darmstadt hand, Karlsruhe hand, University of Bologna (UB) hand ( VIDEO 756,  VIDEO 767), Barrett hand ( VIDEO 752), Yasukawa hand, Gifu hand, U-Tokyo hand, Hiroshima hand, Soft Pisa/IIT hand ( VIDEO 749,  VIDEO 750), and many others [19.4–10].

When designing a multifingered hand, on the basis of its utilization, one should first define the following key issues: number and kinematic configuration of the fingers, anthropomorphic or nonanthropomorphic aspect, built-in or remote actuation, transmission system (in case of remote actuation), sensor assignment, integration with a carrying device (robot arm), control. All these aspects are considered in this chapter.

19.1 Basic Concepts

Before illustrating the main issues involved in the design and use of a robotic hand, it is necessary to discuss some basic concepts and definitions often encountered when dealing with these devices. In particular, terms like *dexterity* and *anthropomorphism* must be defined, and their implications on robotic hand design specified.

19.1.1 Anthropomorphic End-Effectors

The term *anthropomorphism* denotes the capability of a robotic end-effector to mimic the human hand, partly or totally, as far as shape, size, consistency, and general aspect (including color, temperature, and so on) are considered. As the word itself suggests, anthropomorphism is related to the external perceivable properties, and is not, itself, a measure of what the hand can do. On the contrary, *dexterity* is related to actual functionality and not to shape or aesthetic factors. In this sense anthropomorphism and dexterity are *orthogonal* concepts, whose reciprocal dependance (at least in the robotic field) has been not proved yet.

As a matter of fact, we can find in the literature anthropomorphic end-effectors with very poor dexterity level, even though they are called *hands*, as the tasks they can perform are limited to very rough grasping procedures [19.11]. Similarly, we can find smart end-effectors, capable of sophisticated manipulation procedures, without any level of anthropomorphism, e.g., the DxGrip-II [19.12]. Anthropomorphism itself is neither necessary nor sufficient to achieve dexterity, although it is quite evident that the human hand achieves a very high level of dexterity and represents a preferential paradigm for dexterous robotic manipulation.

Anthropomorphism is a desirable goal in the design of robotic end-effectors mainly for the following reasons:

- The end-effector can operate in a human-oriented environment (e.g., servicing robots), where tasks may be executed by robots or men as well.
- The end-effector can be tele-operated by a human operator, by means of special-purpose interfaces (e.g., a data-glove), directly reproducing the operator's hand behavior.
- For purposes of entertainment, assistance, and so on, a human-like aspect and behavior may be specifically required, like for humanoid robots.
- For prosthetic devices anthropomorphism is a quite evident design goal. The development of end-effectors for prosthetic purposes [19.13–15] has recently produced so advanced devices that they can be fully considered robotic systems.

While it is difficult to quantify the effective degree of dexterity of a robotic system, its anthropomorphism can be defined in a precise and objective way. In particular, the aspects that mainly contribute to determine the anthropomorphism level of a robotic hand are:

- *Kinematics*: concerning the presence of the main morphological elements (principal upper fingers, secondary upper fingers, opposable thumb, palm).
- *Contact surfaces*: extension and smoothness of the contact surfaces, aspect that reflects on the capability to locate contacts with objects all over the surface of the available links and on the presence of external compliant pads [19.16].

- *Size*: i. e., the size of the robotic hand both referring to the average size of a human hand and the *correct* size ratio between the links.

19.1.2 Dexterity of a Robotic Hand

Besides the *geometrical* reproduction of the human hand, the main research target remains the emulation of those functionalities which make it such a versatile end-effector.

Two are the main capabilities of a human hand:

- *Prehension*, i. e., the hand's ability to grasp and hold objects of different size and shape
- *Apprehension*, or the hand's ability to understand through active touch.

In this sense, the human hand is both an *output* and *input* device [19.17]. As output device, it can apply forces in order to obtain stable grasps or perform manipulation procedures. As input device, it is capable to explore an unknown environment providing information about the state of the interaction with it. The same features are desirable in robot hands. As a matter of fact, the application of robotic systems in unknown environments requires dexterous manipulation abilities to execute complex operations in a flexible way.

A widely accepted definition states that the dexterity of a robotic end-effector is a measure of its capability of changing the configuration of the manipulated object from an initial configuration to a final one, arbitrarily chosen within the device workspace. Generally speaking, with the term *dexterity* we intend the

capability of the end-effector, operated by a suitable robotic system, to autonomously perform tasks with a certain level of complexity. An exhaustive review of scientific work developed so far about dexterity of robotic hands, with a quite complete and updated list of references, can be found in [19.18].

Even though the word dexterity itself has a very positive meaning, it may be useful to consider different levels of dexterity, associated with growing complexity and criticality of performable tasks. The dexterity domain for robotic hands can be roughly divided in two main areas, i. e., *grasping* and *internal manipulation*.

Grasping is intended as the capability of constraining objects with a constraint configuration that is substantially invariant with time (the object is fixed with respect to the hand).

Internal manipulation is a controlled motion of the grasped object in the hand workspace, with the constraint configuration changing with time.

Further subdivisions of these two domains have been widely discussed in the literature (different grasp topologies [19.19], different internal manipulation modes based on internal mobility and/or contact sliding or rolling [19.18]).

Although the notion of dexterity is well settled, the way to achieve it remains debated. Factors affecting the actual capabilities of a robotic end-effector are so many that often the analysis and above all the synthesis of dexterous hands do not take into proper consideration some of these elements, namely: morphological features; sensory equipment; control algorithms; task planning strategies; and so on.

19.2 Design of Robot Hands

The mechanical design of an articulated robotic hand can be performed according to many possible design concepts and options, even if a kinematical architecture has already been defined and size and shape specifications imposed. One of the main issues is the design of a proper actuation and transmission system. This aspect is crucial because space and dimensions are usually limited, being in general an anthropomorphic aspect and dimension a design goal to be pursued. Another aspect that is relevant for the design is the adoption of compliant structures (Fig. 19.1), in place of conventional mechanical joints, e.g., rolling pairs [19.20, 21].

Note that, since many solutions and operating concepts can be adopted, what is presented here aims only at illustrating the most significant solutions, and does

not pretend to be a complete discussion of all the possible choices.

19.2.1 Actuators Placement and Motion Transmission

In order to actuate the joints of a robot hand, two basic approaches for the placement of the actuators are possible, i. e.:

- Placing the motors as close as possible to each joint, directly in the fingers and sometimes integrating them within the joint itself.
- Placing the motors into the palm or in the forearm; in this case motion is transmitted to each joint by means of (complex) kinematic chains.

Fig.19.1a–c
Three robotic fingers based on compliant joints. (a) The finger is obtained in a single teflon piece; (b) joint compliance is achieved with metallic springs; (c) fast prototyping allows for different compliant mechanisms as joints

In-site actuation can be defined as the case in which the actuator is hosted inside one of the two links connected by the actuated joint or is placed directly inside the joint:

- *Direct-drive actuation*: the actuator is placed directly on the joint, without transmission elements.
- *Link-hosted actuation*: the actuator is placed inside one of the two links constituting the actuated kinematic chain.

In-site actuation simplifies the mechanical configuration of the joint, reducing the transmission chain complexity. In particular, it has the great advantage that the motion of the joint is kinematically indepen-

dent with respect to other joints. Usually, the size of the finger is imposed by the dimension of the actuators, and for technological reasons it is quite difficult to obtain both an anthropomorphic size and the same grasp strength of the human hand. Furthermore, the motors occupy a large room inside the finger structure, and it is a serious problem to host other elements, like sensors or compliant skin layers. A further negative aspect is that, since the mass of the actuators is concentrated inside the finger, the dynamic behavior of the system and its response bandwidth are reduced.

Nevertheless, the recent advancement of actuator technology enables us to directly implement a quite powerful actuator with reasonable size in each joint.

This built-in actuation has been adopted, e.g., for **DLR** hand [19.4, 22], **ETL** hand, Karlsruhe hand, Yasukawa hand, Barrett hand, Gifu hand, U-Tokyo hand, and Hiroshima hand. Since this actuation does not include compliant element like tendons, we can keep a stiff transmission system, which leads to a stable control system even under a high gain (Sect. 19.4). An issue is the routing of wires for both power and signal cables. This issue is more serious in distal joints than for the base joint, since the cables in distal joints produce a relatively large torque disturbance on the first joint, and therefore it is difficult to achieve a precise torque control for this joint.

Remote Actuation

Remote actuation is an alternative solution to in-site actuation. In remote actuation, the joint is driven by actuators placed outside the links connected by the joint itself. Remote actuation requires a motion transmission system, that must pass through the joints between the motor and the actuated joint. In some way, remote actuation must consider the problem of kinematic coupling between the actuated joint and the previous ones. Remote actuation is prevalent in biological structures (e.g., in human hand), where the finger joints are moved by muscles placed on the palm or in the forearm. This human-like approach has been adopted in projects of robotic hands like the **UB** hand or the National Aeronautics and Space Agency (**NASA**) Robonaut hand [19.23, 24].

Remote actuation systems can be classified according to the type of adopted transmission elements, i. e., flexible- or rigid-link transmission.

Flexible Link Transmission. Flexible link transmission is based on deformable connections, either flexible or rotational, that can adapt to variations of configuration by changing the transmission path. Linear flexible transmissions are based on flexible elements with translating motion, subject to tension (more frequently) or tension and compression. Two further subcategories can be identified: pulley-routed flexible elements (tendons, chains, belts) or sheath-routed flexible elements (mainly tendon-like elements). Rotational flexible transmissions are based on flexible rotary shafts, that can transmit rotational motion inside the finger structure to the joint, where a final transforming mechanism (a bevel gear or a worm gear) can be used to actuate the joint.

Rigid Link Transmission. Rigid link transmission is mainly based on articulated linkages or on rolling conjugated profiles (mainly gear trains). A further subdivision can be made between parallel and nonparallel

axes gear trains, like bevel gears, worm gears, and so on.

19.2.2 Actuation Architectures

Both in-site and remote actuation can be applied according to different types of organization, i. e., by using one or more actuators for each joint and by making these actuators work in different ways.

In general, we can consider an overall number N of joints for the robotic hand (the wrist joints are not considered) and a number M of actuators that are used to drive, directly or indirectly, the joints. According to different concepts of actuation and transmission, three main categories of actuation schemes can be identified:

- $M < N$: some joints are passive, coupled, or underactuated.
- $M = N$: each joint has its own actuator and there are no passive, coupled or underactuated joints.
- $M > N$: more than one actuator is operating on a single joint.

These architectures strongly depends on the type of motors. In particular, it is possible to recognize two main actuation modalities:

- *Single-acting actuators* – each motor can generate a controlled motion in one direction only: return motion in opposite direction must be obtained by an external action, that can be a passive (e.g., a spring) or an active system (e.g., an antagonistic actuator); this is the case of tendon-based transmission systems.
- *Double-acting actuators* – each motor can generate a controlled motion in both directions and can be used alone to drive the joint or to cooperate with other actuators; in this case the functional redundancy can allow sophisticated drive techniques, like push-pull cooperation.

Each category can be further subdivided. In the following, a brief description of the most frequently adopted schemes is presented.

Single-Acting Actuators with Passive Return Elements

Passive elements, like springs, can store energy during the actuation phase, restituting it during the return stroke (Fig. 19.2a). This mechanism leads to a simplification of actuation scheme, but requires mechanically backdrivable actuators. Other possible drawbacks are related to the loss of available power for the grasp and

the limited response bandwidth in case of low spring stiffness.

Agonistic-Antagonistic Single-Acting Actuators

Two actuators drives the same joint, acting in opposition in different directions (agonistic-antagonistic couple) (Fig. 19.2b). This solution leads to an N joints- $2N$ actuators scheme and is quite complex since a large number of actuators must be placed in the hand. On the other hand, it may allow sophisticated control procedures, as both actuators can pull at the same time, with different intensity, generating a driving torque on the joint and a preloading of the joint itself (cocontraction, typical of tendon-driven joints):

- *Pros*: cocontraction strategies, possibility to change the joint stiffness according to the grasping phase and therefore to limit the influence of friction during fast approaching motions; independent position/tension control on each actuator can allow compensation of different path length in case of remote transmission; it is the most flexible solution for driving a joint.
- *Cons*: back-drivability of actuators is required; high difficulty in hosting two actuators for each joint, both in in-site and in remote location; higher control complexity; higher cost.

Single-Acting Actuators Organized According to the Concept of Actuation Net

This is a very interesting case, mimicking biological systems, but has not been implemented yet in robotic hands, except for some preliminary studies. N joints are driven by M actuators, being $N < M < 2N$. Each actuator cooperates in moving more than one joint, thanks to proper net-shaped transmissions:

Fig.19.2a,b Single-acting actuator with an antagonist passive element (a) and in an agonist-antagonist configuration (b)

- *Pros*: cocontraction strategies, possibility to change the joint stiffness according to the grasping phase and therefore to limit the influence of friction during fast approaching motions; reduced number of actuators with respect to the $2N$ actuators scheme.
- *Cons*: back-drivability of actuators is required; high complexity of the kinematic scheme and therefore high complexity in control.

The simplest case of actuation net is represented by the so called $N + 1$ actuation (being N in this case the number of joints of a finger), frequently adopted in practice (Fig. 19.3). In this case, all actuators are coupled, and therefore a damage of any of them will result in a general failure.

Double Acting Actuators with $M < N$

In this case, the number of actuators is less than the number of joints. With reference to a single motor and several joints, two main subcases can be defined:

1. The joints are kinematically coupled, in a fixed or variable way, so that the number of degrees of freedom of this subsystems is reduced to one.
2. The joints are selectively actuated by the motor, according to an active or passive selection subsystem.

The former case can be further subdivided:

- *Joints kinematically coupled in a fixed way*: In this kind of kinematical configuration, each motor can move more joints connected by rigid mechanisms with fixed transmission ratios. A typical application is obtained with the use of a gear train: the first link is directly actuated by a motor, while a gear transmission between a wheel fixed to the frame and a final wheel connected to the joint generates the relative motion of the second link (Fig. 19.4a). Should the motion of two parallel fingers be required, their connection could be easily obtained mounting two gear wheels on the same shaft. Another very common way to obtain this kind of kinematical linkage is to use tendon driven devices

Fig.19.3a-c Remote actuation. (a) N -type, (b) $2N$ -type, (c) $N + 1$ -type

as shown in Fig. 19.4b. In artificial hand design, the main advantage when using joints driven by fixed-ratio mechanisms is the possibility to know and control the position of the second link. A disadvantage is that this kind of mechanisms does not adapt to the shapes of the grasped objects, and this may cause grasp instability.

- Joints coupled in a non-fixed way:** This is the case of underactuated mechanisms and deformable passive-driven joints. A mechanism is said to be *under-actuated* when the number of actuators is smaller than the number of degrees of freedom. When applied to mechanical fingers, this concept may lead to shape adaptation, i.e., underactuated fingers can envelope the objects to be grasped and adapt to their shape even with a reduced number of actuators. In order to obtain a statically determined system, elastic elements and mechanical limits must be introduced in underactuated systems (simple linear spring are often used). In the case of a finger closing on an object, for instance, the configuration of the finger is determined by the external constraints associated with the object. An example of an underactuated two-degrees of freedom finger is shown in Fig. 19.5 [19.25]. The finger is actuated through the lower link, and a spring is used to maintain the finger fully extended. A mechanical limit is used to keep the phalanges aligned under the action of this spring when no external forces are applied on the phalanges. Since the joints cannot be controlled independently, the behavior of the finger is determined by the design parameters (i.e., the geometric and the stiffness properties). Hence, the choice of these design parameters is a crucial issue.

Another approach consists in coupling the motion of two adjacent joints by means of deformable linkages. This feature introduces in the kinematical chain the needed compliance to fit to the shapes of the grasped objects. A very simple mechanism of this category is reported in Fig. 19.6. Structurally it is similar to the mechanisms based on a fixed coupling, the only important difference is the addition of a spring to give extensibility to the tendon. This spring allows to decouple the motion between the first and second link when an external force is applied to the distal one. This solution is widely used: a well known example is the **DLR** hand. The benefits of this solution are mainly due to the possibility to fit to the shapes of objects. A design problem is the choice of the stiffness of the deformable element in order to achieve at the same time a strong grasp and a good shape adaptability.

- Joints selectively driven by only one motor:** With this solution, the motion generated by only one

(large) motor is transmitted and distributed to several joints. Actuation and control of each joint is obtained by means of insertion-disinsertion devices like self-acting or commanded clutches.

Double-Acting Actuation, with $M = N$

This is a very common case: each joint is driven in both directions by the same actuator. The achievable performances are therefore similar (equal) in both directions, but particular attention must be paid to backlash, and it is usually necessary to preload the transmission system. In particular, preload is mandatory in case of transmission by means of flexible elements like tendons (Fig. 19.3a). Furthermore, the adoption of a closed-

Fig. 19.4 Double-acting actuator with $N = M$ based on gears (a) and tendons (b)

Fig. 19.5a–d Grasping sequence performed by a finger based on underactuated mechanism

Fig. 19.6 Joints coupled in non fixed way

loop tendon transmission requires that the overall length of the tendon route must be kept constant, according to the concept that winded and unwinded parts of the tendon on the motor pulley have the same length; this involves the need of length-compensating mechanisms (e.g., pulley-trains, cams) every time that changes in the geometry of the finger cause a differential displacement of the tendons. In spite of this

required complexity, this actuation scheme has been widely used, with simple pulley routing (UB hand, Okada hand, ...), or sheath-routing (Salisbury hand, Dipartimento di Informatica Sistemica e Telematica (DIST) hand), that has a simpler mechanical structure but must face the problem of sheath-tendon friction (application of high preload is not convenient in this case).

19.3 Technologies for Actuation and Sensing

In this Section, a brief description of the main issues related to technological aspects of actuation and sensing for robot hands is reported. A more general presentation and detailed description of these aspects is given in Part A (Chaps. 4 and 5) and Part C (Chap. 28).

19.3.1 Actuation

Electrical actuators are without doubt the most common choice for actuating robot hands. As a matter of fact, electric motors have very good performance in terms of position/velocity control, have a reasonable mass/power ratio, and are a very common technology, that does not require external devices (as for hydraulic or pneumatic actuators). However, there are several other possibilities. For example: ultrasonic motors (Keio hand [19.26]), chemical actuators, pneumatic actuators (McKibben in the Shadow hand [19.27]; [VIDEO 753](#)), spring based actuators (as for the 100G Capturing Robot [19.28] [VIDEO 755](#)), twisted string actuators (Fig. 19.7) [19.29] (Dexmart hand [19.30]; [VIDEO 767](#)), and others.

In particular, for pursuing quick responses, either pneumatic or spring-based actuators may be good solutions, although it should be noted that a braking system

with quick response is essential for achieving good position controllability for this type of actuators.

19.3.2 Sensors

In robot hands, as in other robotic devices, sensors can be classified in two main categories: *proprioceptive* and *exteroceptive* sensors. The first type of sensors measures physical information related to the state of the device itself (e.g., position, velocity, and so on), while the second one is devoted to the measurement of data related to the interaction with objects/environment (e.g., applied forces/torques, friction, shape, and so on).

Joint Position/Velocity Sensors

For control purposes, there is the obvious necessity of measuring position/velocity of the actuated joints. A major problem consists in the limitation of the available space, both for the sensors and for the wires. Different technological solutions can be adopted, but a rather common choice is based on Hall-effect sensors, that are sufficiently small, precise and reliable for this type of application. In case of remote actuation, there is the possibility of having two position/velocity sensors for each joint: one located in the actuator (e.g.,

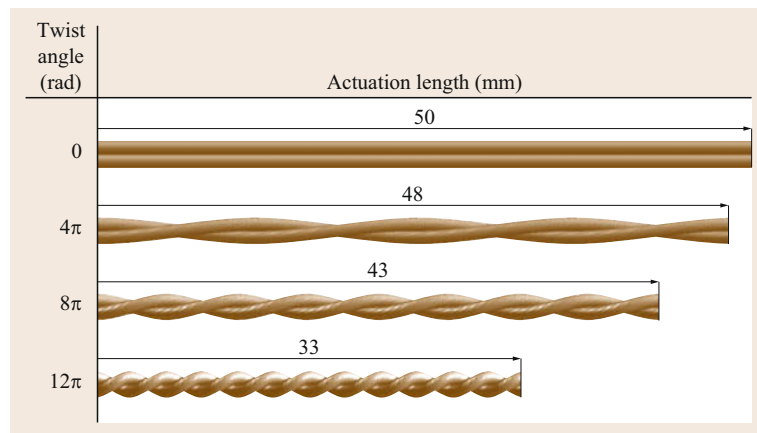

Fig. 19.7 The twisted string concept: by twisting the string, its twisted string concept length is reduced transforming a rotational motion into a linear one

an encoder) and one placed in the joint itself, often necessary because of the non linearities introduced by the transmission system (elasticity, friction, and so on). Quite often, this latter sensor is specifically designed and implemented for the given hand, being commercially available sensors too large and not suitable for installation in the joints.

Tendon Tension Sensor and Joint Torque Sensor

It is well known that humans can control finger tip compliance as well as finger tip force by controlling voluntary muscles. In remote actuation, it is essential to measure the tendon tension for two main reasons: for compensating the friction existing in the transmission system, and for measuring the external contact force. Figure 19.8 shows a way for measuring the tendon tension where the tendon is pressed by an elastic plate with a strain gauge. When a tension is applied to the tendon, the sensor measures a force composed of axial and bending force components. The displacement of the elastic plate due to the axial force component is negligibly small compared with that due to the bending force component. As a result, the bending force component generates a bending deformation for the elastic plate. This deformation is transformed in an electric signal by means of proper transducers, such as strain gauges attached on the surface of the plate or optoelectronic components [19.31, 32]. Now, suppose N -type actuation with two tension sensors, as shown in Fig. 19.9, where joint torque τ is given. Note that $\tau = r(T_1 - T_2)$

Fig. 19.8 Tendon tension sensing

Fig. 19.9 Tension sensor based torque sensing

where r , T_1 , and T_2 are the pulley radius and tendon tensions, respectively. Since we can measure e_1 and e_2 corresponding to T_1 and T_2 , τ can be obtained by feeding both e_1 and e_2 into the differential circuit. This approach, however, includes a couple of issues. The main problem is the plastic deformation of the sensor plate under an extreme large pretension. Once such a plastic deformation has happened, the sensor will never work appropriately anymore. Another minor issue is that two sensors are always necessary for measuring a joint torque. To cope with these issues, the tension-differential-type torque sensor [19.28] can be used as shown in Fig. 19.10. The sensor is designed with just a single body and it partially includes an elastic part where at least one strain gauge is attached. The working principle of the sensor, shown in Fig. 19.10a, supposes that a torque is applied to the joint. This means that T_1 and T_2 have different values. This difference causes a bending force around the strain gauge. The key is that the bending force is kept to zero even under an extremely large tension as far as no joint torque is given. Therefore, we are completely released from the plastic deformation of the elastic plate due to pretension. Furthermore, the sensor is constructed with just a single body. There are couple of variations in this type of torque sensor. As decreasing the pulley distance in Fig. 19.10a, the sensor eventually results in the single-pulley-version with zero distance, as shown in Fig. 19.10b. The single-pulley-version has been implemented into Darmstadt

Fig.19.10a–c Tension-differential type (TDT) sensor. (a) Double pulley version, (b) single pulley version, (c) pulley-less version (after [19.28])

hand [19.33] and MEL hand [19.34]. Furthermore, if the sensor is built in the finger link connected by the concerned tendon, there is no relative motion between the sensor and the tendon. As a result, we can remove the pulley, as shown in Fig. 19.10c. This is called as the pulley-less version and has been implemented into Hiroshima hand. The tension-differential-type torque sensor will be a powerful tool for measuring a tendon drive joint.

Finger Tip Tactile (or Force) Sensors

Most robot manipulation and assembly tasks would benefit of the utilization of tactile sensory information. When lifting an object, tactile sensing could detect the onset of slip in time for corrective action to be taken. In addition to the contact point between the finger tip and the object, several objects properties, such as friction coefficient of the object surfaces, surface texture, and weight can be determined by utilizing a finger tip tactile (or force) sensor. A six-axis force sensor allows us to detect contact point as well as contact force between finger and environment, if a single contact is assumed. For the finger model as shown in Fig. 19.11, the following relationship between the sensor output and contact force may be defined

$$\mathbf{F}_s = \mathbf{f}, \quad (19.1)$$

$$\mathbf{M}_s = \mathbf{x}_c \times \mathbf{f}, \quad (19.2)$$

where $\mathbf{f} \in \mathbb{R}^3$, $\mathbf{F}_s \in \mathbb{R}^3$, $\mathbf{M}_s \in \mathbb{R}^3$, and $\mathbf{x}_c \in \mathbb{R}^3$ are the external force vector, the force vector measured by the six-axis force sensor, the moment vector measured by the six-axis force sensor, and the position vector indicating the contact position, respectively. From the first equation, we can directly obtain the contact force. Putting \mathbf{F}_s into the second equation leads to $\mathbf{M}_s = \mathbf{x}_c \times \mathbf{F}_s$. \mathbf{x}_c is determined in such a way that $\mathbf{M}_s = \mathbf{x}_c \times \mathbf{F}_s$ may be satisfied. For a finger with convex object, we have always two mathematical solutions as shown in Fig. 19.12a where the meaningful solution is the one satisfying $\mathbf{f}^t \mathbf{n} < 0$, \mathbf{n} being the outward normal direction to the finger's surface (a finger can only push the

Fig. 19.11 Sensor coordinate system Σ_s

object). However, for a finger with concave shape, we have at least four mathematical solutions, as shown in Fig. 19.12b where two of those are physically possible. A finger with the six-axis force sensor located in the fingertip, Fig. 19.12c, can avoid multiple solutions. On the other hand, only forces applied to the fingertip can be detected, and if more links are in contact with the object it would be necessary to have a force/torque sensor placed in each of them.

This type of solution, i.e., a multiaxis sensor for measuring not only forces and torques but also the position of the contact point, is known in the literature as the *intrinsic tactile (IT)* principle [19.35]. In general, with respect to the use of traditional tactile sensors, see later, it leads to a simplification in the design since it requires less wires and connections for the sensor.

Tactile Sensors

Another important class of sensing devices consists of tactile sensors, which are used for several purposes, such as shape recognition, contact point determination, pressure/force measurement. A number of tactile sensors have been proposed in the literature, with several different solutions concerning the implementation features: optical, piezoresistive, piezoelectric, and so on. References [19.36, 37] give an overview on technologies and applications.

Fig. 19.12 Interpretation of solutions. (a) Convex shape, (b) finger with a concave shape, (c) sensor located in the fingertip

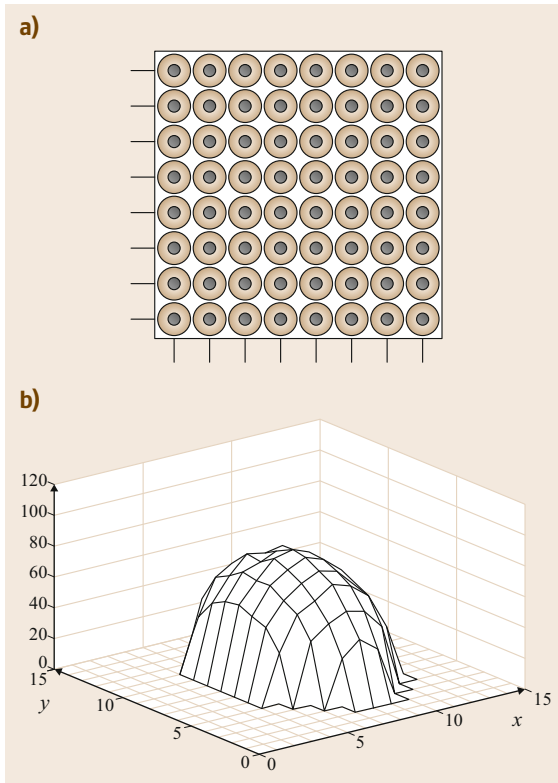

Fig.19.13a,b A Tactile sensor. (a) Scheme of a tactile sensor, (b) example of data from a tactile sensor

Tactile sensors have been introduced in robotics since the late 1970s. Nowadays, as the force sensors, also tactile sensors are commercially available devices. Probably, they represent the most commonly adopted sensorial class for industrial grippers, even though they are often used as advanced *on/off* devices to check whether a grasp or contact condition occurs.

Usually, they consist in a matrix (array) of sensing elements. Each sensing element is usually referred to as a *taxel* (from *tactile element*), and the whole set of information is called a *tactile image*, Fig. 19.13. Main

goal of this class of sensors is to measure the map of pressures over the sensing area.

In general, the types of information that may be obtained from a tactile sensor are:

- *Contact*: This is the most simple information given by the sensor, concerning the presence or absence of a contact.
- *Force*: Each sensing element provides an information related to the amount of locally applied force, which can be used in several manners for successive elaborations.
- *Simple geometrical information*, i. e., position of the contact area, geometrical shape of the contact itself (planar, circular, and so on).
- *Main geometrical features of the object*: By proper elaborations of the data of the taxels, it is possible to deduce the type of object in contact with the sensor, for example a sphere, a cylinder and so on (data relative to the 3-D (three-dimensional) shape).
- *Mechanical properties*, such as friction coefficient, roughness, and so on. Also thermal properties of the object may be measured by a tactile sensor.
- *Slip condition*, i. e., the relative movement between the object and the sensor.

Several technologies have been adopted for the design of tactile sensors, ranging from piezoresistive to magnetic, to optical effects, and so on. Among the most common, one can mention:

- Resistive and conductive effect
- Electromagnetic effect
- Capacitive effect
- Piezoelectric effect
- Optical effect
- Mechanical methods.

Each of these technologies has positive and negative aspects. Common drawbacks, however, are the size of these sensors, usually quite large in comparison with the available space, and the necessity of a high number of electrical connections.

19.4 Modeling and Control of a Robot Hand

The dynamic model of a robot hand with in-site actuation is very similar to the model of a traditional (industrial) robot, and the hand can be considered as a collection of robot manipulators. On the other hand, remote actuation introduces some peculiar features that have to be carefully considered. In particular, the problems tied to nonlinear phenomena (e.g., friction and backlash),

compliance of the transmission system, and noncollocation of sensors and actuators are very critical for the design of the control. Moreover, the use of single-acting actuators, such as tendon based actuation systems, requires the adoption of proper control techniques, which allow the imposition of the desired torque at each joint of the hand, despite the coupling among them.

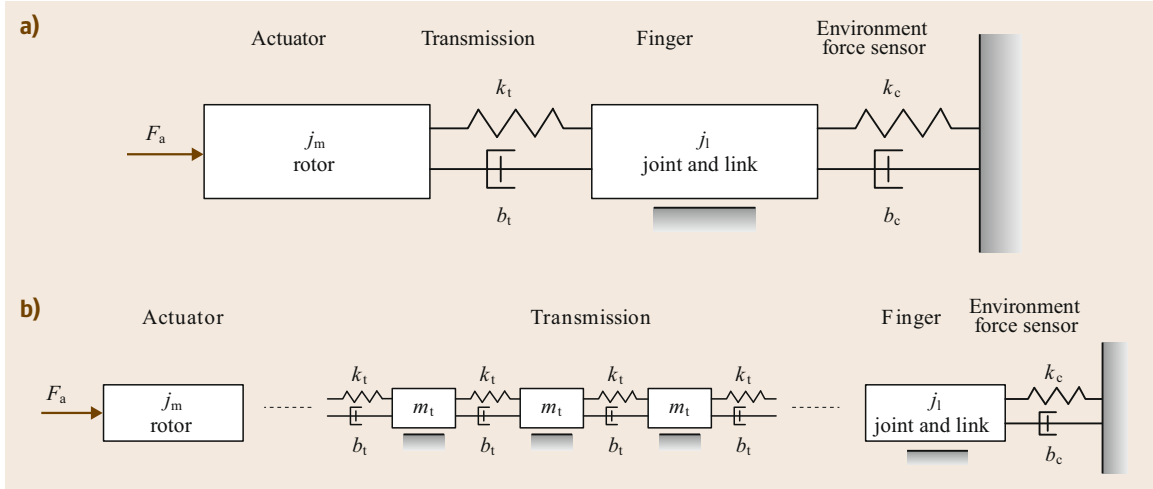

Fig. 19.14a,b Model of a robot joint (a) with transmission flexibility, and (b) with tendon based transmission

19.4.1 Dynamic Effects of Flexible Transmission Systems

The transmission system of robot hands with remote actuation is usually characterized by an high level of friction and non negligible dynamic effects which complicate the control problem. A simple representation considers a single axis motion with two inertial elements linked by an elastic transmission. This is the typical representation of elastic joints in which the former element represents the motor inertia, while the latter is related to the inertial properties of the actuated joint/link (Fig. 19.14a). More complex models assume a dynamic model for the transmission system, i. e., the classical representation of tendons based on the serial repetition of masses linked by springs/dampers, reported in Fig. 19.14b. These simple models are par-

ticularly useful to understand some drawbacks and limitations due to the fact that actuation system and actuated element are located in two different places and the motion is transmitted by a nonideal (that is not purely static) element. If we consider the capability of the fingers' joint of applying a force on the environment, the effect of the transmission system on the open loop response of the system modeled as in Fig. 19.14a, are a noticeable reduction of the bandwidth, and an important phase delay between the input F_a (the force applied by the motor) and the output F_c (the force exchanged at the contact). As shown in Fig. 19.15, the open-loop transfer function

$$\frac{F_a}{F_c} = \frac{(b_c s + k_c)(b_t s + k_t)}{[j_l s^2 + (b_t + b_c)s + k_t + k_c](j_m s^2 + b_t s + k_t) - (b_t s + k_t)^2} \quad (19.3)$$

is characterized by four poles that, for growing values of the transmission stiffness k_s , move from their initial locations (that depend on the values of physical parameters j_l , j_m , etc., although for $k_s = 0$ at least one pole is in the origin of the Gauss plane) towards the poles of a system with an infinitely rigid transmission (for k_c tending to ∞ , two poles go to infinity) (and a total inertia given by the contributions of both the motor and the link) whose transfer function is

$$\frac{F_a}{F_c} = \frac{(b_c s + k_c)}{(j_l + j_m)s^2 + b_c s + k_c} \quad (19.4)$$

As a consequence, the bandwidth of the system with flexible transmission, that for high values of k_s approx-

Fig. 19.15 Root contour of the transfer function (19.3) with variable k_t

Fig. 19.16 Bode plots of the open loop transfer function (19.3) for low stiffness values (*continuous line*) high stiffness value (*dashed line*) and with no transmission (*dotted line*) ►

imates those of (19.4), decreases when the compliance of the transmission is not negligible, see the Bode plots reported in Fig. 19.16. The bandwidth of the system with flexible transmission is strongly affected by the location of the speed reducer: when the reducer is placed at the joint the bandwidth is K_r times (K_r is the reduction ratio) higher than the one achievable with the reduction applied directly on the motor [19.38] (Fig. 19.17). Moreover, it is worth to notice that for low level of the stiffness k_t a sharp phase drop occurs at the frequency of the flexible mode. Therefore, there are some frequencies (relatively low) at which the force applied by the motor and the one measured with a sensor in the finger's joint are completely out of phase. These effects, which may cause the instability of the overall system under force control (or impedance control) are referred to as *noncolocation*. In general, when actuators and sensors are physically located at different points of a flexible structure (or a structure with flexible transmission), there will be unstable modes in the closed-loop system [19.39].

From the control viewpoint, the problem of mechanical transmission flexibility is further exasperated by the non linear frictional phenomena that inevitably affect remote actuation and motion transmission. As a matter of fact, the linear viscous friction, represented in Fig. 19.14 by the damping coefficient b_t , is accompanied by stiction and Coulomb friction, both of which are discontinuous at zero velocity (Fig. 19.18). These nonlinearities may cause limit cycles and input-dependent stability, and must be accurately taken into account in the design of the robot hand structure as well as of its control architecture [19.40]. For instance, in the design of the Utah/MIT dexterous hand, depicted in Fig. 19.19, in order to reduce static friction, the idea of using tendon sheaths was abandoned in favor of pulleys [19.3]. In order to find an optimal trade-off between complexity and reliability of the mechanical arrangement and achieved friction level, a number of solutions, which combine sheaths and pulleys for routing the tendon from actuators to fingers' joints has been adopted in the design of robot hands, e.g., the Stanford/JPL hand (VIDEO 751) and the UB hand 3 reported in Fig. 19.20. This device is characterized by an extremely simple structure, with the tendons completely routed within sheaths, but on the other hand the friction cannot be absolutely neglected and a precise modeling of the interaction between the tendons and the tube is necessary for control purposes [19.41].

Fig. 19.17 Reducer location on the medial joint of the DLR hand II

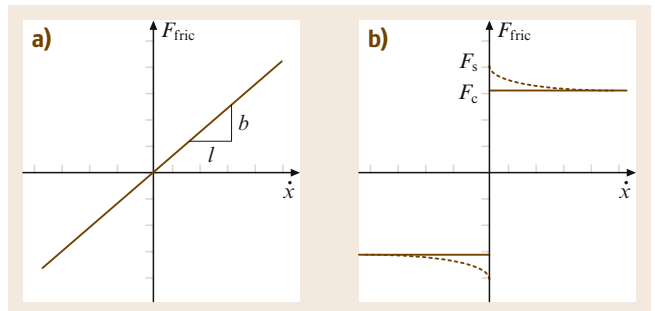

Fig.19.18a,b Frictional phenomena: viscous friction (a) and stiction and Coulomb friction (b)

19.4.2 Transmission Model of Tendon-Outer-Tube System

This system can be modeled as shown in Fig. 19.21 where T_{in} , T_{out} , T_0 , ξ_{in} , ξ_{out} , R_1 , x , and L are the tension at the input side, the tension at the output side, the initial pretension, the displacement at the input side, the displacement at the output side, the local radius of routing, the coordinate system along the wire, and the length of the tendon, respectively. The relationship between the tension at output and the input displacement is given by [19.42],

$$T_{out} - T_0 = K_t(\xi_{in}\phi_B), \quad (19.5)$$

Fig. 19.19 The Utah/MIT robotic hand

Fig.19.20a,b Tendon based robot hands: Stanford/JPL hand (a) and UB hand 3 (b)

where K_t and ϕ_B are the total stiffness and the equivalent backlash, respectively, and those are given by,

$$\frac{1}{K_t} = \frac{1}{K_e} + \frac{1}{K_s} + \frac{1}{K_{ap}} \quad (19.6)$$

$$K_{ap} = K_w \frac{\lambda}{\exp(\lambda) - 1} \quad (19.7)$$

$$\phi_B = \frac{T_0 L}{EA} \cdot \frac{\exp(\lambda) - \lambda - 1}{\lambda} \quad (19.8)$$

$$\lambda = \sum |\beta_i| \mu \operatorname{sgn} \xi_{in} \quad (19.9)$$

where K_e , K_s , K_w , K_{ap} , μ , E , A and β_i are the stiffness of environment, the stiffness of force sensor, the apparent stiffness of the tendon, the friction coefficient, Young's modulus, the cross sectional area, and the bending angle of each segment of tendon, respectively. For example,

$$\sum |\beta_i| = 2\pi$$

for the case given in Fig. 19.21. As can be seen from this example, the friction related parameter λ increases dramatically when the tube is heavily bent. While we have a big advantage of choosing a free route for the power transmission, it brings a large nonlinearity for the transmission system. We would note that while both the apparent stiffness of the tendon and the equivalent backlash vary depending upon λ which is the function of the curvature of the route as well as the friction coefficient, ϕ_B and K_{ap} result in $\phi_B = 0$ and $K_{ap} = K_w$ under $\mu = 0$. From the view point of control, such hysteresis is, of course, not desirable. To cope with these issues, each tendon should be designed as short as possible, so that we may keep high stiffness and small backlash in the transmission system.

19.4.3 The Control Through Single-Acting Actuators

The use of single-acting actuators (i.e., standard motors with tendinous transmission), which are commonly

Fig. 19.21 Model of tendon-outer-tube transmission

assumed in the design of robot hands with remote actuation, requires the adoption of specific control techniques in order to guarantee the desired torques at the joints and to maintain at each time a positive tension on the tendons. To this purpose, the tendons are treated like inelastic frictionless elements and the problem is coped in a way completely decoupled from the issue of the device stability, discussed in previous sections.

A tendon, routed in the finger structure through sheaths or/and pulleys, can be modeled by means an *extension function* $l_i(\theta)$ [19.43] relating the joints' configuration with the tendon elongation. In the case of the tendon network represented in Fig. 19.3, the extension functions of the three tendons have the form

$$l_i(\theta) = l_{0i} \pm R\theta_1 \pm R\theta_2 ,$$

where R is the radius of the pulleys and

$$\theta = [\theta_1 \theta_2]^T$$

is the vector of the joint variables. Once the extension function has been determined, it is straightforward to derive the relationship between tendons forces and resulting joints torques. As a matter of fact, the relation between the joint speeds $\dot{\theta}$ and tendon speeds \dot{l} can be deduced by simply differentiating the expression of extension functions

$$\dot{l} = \frac{\partial l}{\partial \theta}(\theta) \dot{\theta} = \mathbf{P}(\theta) \dot{\theta} . \quad (19.10)$$

Because of the conservation of the power, from (19.10), one can achieve

$$\tau = \mathbf{P}^T(\theta) f , \quad (19.11)$$

where τ are the torques exerted on the joints, and f are the force applied by tendons. From (19.11) it results that the force transmitted by a tendon may affect (and, in general, will affect) more than one joint.

In order to guarantee the possibility of exerting joint torques in every direction under the constraint of pure tensile forces, for any $\tau \in \mathbb{R}^n$ it must exist a set of forces $f_i \in \mathbb{R}^m$ (n and m are respectively the number of

joints and the number of tendons) such that

$$\tau = \mathbf{P}^T(\theta) f \quad \text{and} \quad f_i > 0, i = 1, \dots, m . \quad (19.12)$$

In this case the tendon network is said *force closure*. If the condition expressed by (19.12) is verified, given a desired torque vector τ it is possible to compute the force that the actuators must provide to the tendons according to

$$f = \mathbf{P}^\dagger(\theta) \tau + f_N , \quad (19.13)$$

where

$$\mathbf{P}^\dagger = \mathbf{P}(\mathbf{P}^T \mathbf{P})^{-1}$$

is the pseudo-inverse of the coupling matrix \mathbf{P}^T and

$$f_N \in \mathcal{N}(\mathbf{P}^T)$$

is a vector of *internal forces* that insures that all tendon tensions are positive. In general, internal forces will be chosen as small as possible, so that the tendons are always taut but are not subject to excessive strains.

19.4.4 Control of a Robot Hand

The modeling and control aspects described in the previous Sections, although very important and fundamental, can be considered as a sort of *low level* problems in the control of a robot hand, in the sense that they are related to the specific physical properties of the device.

There are also other problems that must be faced and solved in order to operate in a profitable manner with a multifingered hand. These problems are solved by a proper design of a *high level* control for the hand, that must take into account the interaction of the hand with the objects and more in general with the environment. In this context, general aspects that must be considered are: the control of forces/torques applied at the contact points, the necessity to model contact compliance/friction effects, the type of mobility both for the fingers and at the contact (rolling, sliding, ...), a suitable planning algorithm for grasping and/or manipulating the objects, and so on.

These problems are illustrated in detail in Part C, Chaps. 37–39.

19.5 Applications and Trends

In the industrial environment, simplicity and cost are the main guidelines for the design of end-effectors, and therefore simple devices, as open-close grippers,

are very common and widely used. This situation has led during the years to the development of a number of special-purpose devices, optimized for single

specialized operations but not suitable for other tasks. At the moment, dexterous multifingered hands have not really been applied to any major application, mainly because of problems of reliability, complexity, cost.

On the other hand, more and more operations are currently envisaged for robots working in environments designed for, and utilized by, human operators. Entertainment, maintenance, space/underwater applications, help to disable persons are just a few examples of use of robotic systems in which interaction with tools and objects designed for human beings (or directly with them) is implied. In all these circumstances, the robot must be able to grasp and manipulate objects (different in dimension, shape, weight, ...) similarly to humans, and therefore a robot hand, with a proper number of fingers and joints and also with an anthropomorphic appearance, seems to be the most adequate solution.

There are several projects aiming at developing anthropomorphic robots. Among others, one can mention

Fig. 19.22 The NASA/JPL Robonaut

the NASA/JPL Robonaut [19.24], Fig. 19.22, the devices developed at the DLR, the several projects on humanoid robots currently under development.

19.6 Conclusions and Further Reading

The design of multifingered robot hands has attracted the interest of the research community since the early days of robotics, not only as a challenging technical problem itself but, probably, also because of anthropomorphic motivations and the intrinsic interest for a better knowledge of the human beings. In the last decades, as previously discussed, several important projects have been launched, and important examples of robot hands developed. Nevertheless, the current situation is that reliable, flexible, dexterous hands are still not available for real applications. For these motivations, it is easy to foresee also for the future a consistent research activity in this fascinating field, with developments at the technological (sensor, actuator, material, ...) and methodological (control, planning, ...) level.

Important connections with other scientific fields are also expected, as for example with cognitive science.

Being this research area so wide, it is not simple to suggest to interest readers further readings, except for quite classical books such as [19.43–45]. As a matter of fact, depending on the specific research area, many publications are available, although often not organized as reference books, but mainly as technical papers published in journals or presented at international conferences. Moreover, since hundreds of new papers are published every year covering the different aspects of this robotic field, it is really quite difficult, and also not fair, to give at the moment specific suggestions for further readings. We can only refer to the citations already provided in the references.

20. Snake-Like and Continuum Robots

Ian D. Walker, Howie Choset, Gregory S. Chirikjian

This chapter provides an overview of the state of the art of snake-like (backbones comprised of many small links) and continuum (continuous backbone) robots. The history of each of these classes of robot is reviewed, focusing on key hardware developments. A review of the existing theory and algorithms for kinematics for both types of robot is presented, followed by a summary of modeling of locomotion for snake-like and continuum mechanisms.

20.1 Snake Robots – Short History

The study of snake robots began in earnest with the pioneering work of Shiego Hirose, a professor at the Tokyo Institute of Technology. He called his snake robots these active chord mechanisms, or **ACMs** for short. The first successful locomotive snake was **ACM III** (Fig. 20.1a), which he developed between 1972 and 1975; the **ACM III** robot had 20 segments and used passive wheels to form a constraint between the mechanism and the environment. Each segment was able to yaw with respect to each other and the combined motion of these degrees of freedom propelled the entire robot forward [20.1]. This type of coordinated control resulting in locomotion is called a *gait*; more formally, a gait is a cyclic motion in the mechanisms internal degrees of freedom that result in net motion for the snake robot. The next step in the development of the Hirose family of snake robots were the **OBLIX** (Fig. 20.1b) (1978–1979) and **MOGURA** (1982–1984), two robots that could achieve three-dimensional movements and lift their heads by rotating their oblique joints. The benefit of a single actuator operating an oblique joint over a true three-dimensional joint is simplicity, light weight, and ease to control because each segment only needed to be actuated by one motor [20.2].

Hirose's lab then began exploring possible applications of snake robots with **Koryu I** and **II** (1985–present). Each one of Koryu's load-bearing modules uses actuated joints to lift itself, lower itself, and in more recent incarnations, angle its wheel base to fit the ground. With such forms of actuations, these large snake robots were able to traverse uneven terrain and even climb stairs, all while carrying a load, distributed along the entire robot [20.2]. Inspired by the ability of real snakes to traverse uneven terrains, Hirose's lab developed a smaller mechanism, called **Souryu I** and **II** (1975–present) for the purposes of search and rescue (Fig. 20.2). The **Souryu** robots were able to climb over rubble because of their low center of mass and treads all along their bodies [20.3, 4].

In 1999, *Hirose* returned to the **ACM** with **Slim Slime**, a robot that was pneumatically actuated and formed a smooth curve instead of the usual sectioned, angular curve of other snake robots [20.5]. After **Slim Slime**, the lab began working on **ACM-RI**, **R2**, **R3**, and **R4** (2001–present.) These robots are much closer to the design of the first **ACM**, with passive wheels and many-sectioned bodies. These robots, unlike the first **ACM**, can lift their bodies and move in three dimensions. Each

section has wheels that are set 90° from each other in an alternating fashion. They were created for use in search and rescue [20.1]. The most recent ACM is R5, a fully amphibious robot that uses passive wheels to roll along the ground and paddles to move through the water [20.6] (Fig. 20.3).

Snake robot research began in the United States in the late 1980s. Joel Burdick and his then-student Greg Chirikjian at Caltech developed a continuum theory to model the shape of snake robots in general. Burdick and Chirikjian coined the term *hyper-redundant manipulator*, which means a mechanism that has many more degrees of freedom than are necessary to position and orient its end-effector. They built Snakey in 1992; Snakey consisted of three degree of freedom bays or actuated trusses that could both manipulate and locomote. Their focus was to create a strong, precise mechanism that focused less on snake-like movement and more on the difficulties of programming a mechanism with many degrees of freedom. The Caltech team considered applications such as retrieval of satellites and search and

rescue [20.7, 8]. Burdick and his group also designed and built snake robots with the Jet Propulsion Laboratory and the NEC Corporation with Nobuaki Takanashi. These were based on a three-dimensional joint prototype built by Takanashi. This smaller snake was able to execute several movement gaits, and was intended to be used in search and rescue.

Chirikjian moved on to Johns Hopkins University where he created a comprehensive research program on a broad class of hyper-redundant mechanisms, not limited to snake robots. One such nonsnake robot was the metamorphic shape-changing modular robot system comprising hexagonal elements. His group also developed snake robots based on binary actuators, which have two states, say fully elongated and contracted [20.9].

Snake and reconfigurable modular robot research also co-developed at Xerox Parc, and then at the University of Pennsylvania under the direction of Mark Yim. Beginning with PolyPod [20.10] in 1994 as part of Mark Yim's dissertation while he was at Stanford, snake configurations of modular robots were performing many of the conventional snake gaits as well as some innovative slinky-like and rolling gaits [20.11]. This research continued after Yim's move to Xerox's Palo Alto Research with PolyBot in 2000, a more robust version of PolyPod with more abilities for sensing [20.12]. When Yim began Modlab at the University of Pennsylvania, PolyBot evolved into CKbot ([20.13], 2009). CKbot can now reconfigure from an exploded position, run on four legs, walk on two, and perform most basic snake gaits [20.14, 15]. They also developed foamBot (2011), a robot that can create other robots, including snake robots, out of CKbot modules and hardening spray foam [20.16].

Hirose, Chirikjian, Burdick, and Yim had a strong influence on Howie Choset's work at Carnegie Mellon University (CMU). Choset's snake robot research began in the CMU Biorobotics Lab as an undergraduate research project which adapted Yim's modular design specifically for snake robot use (Fig. 20.7). Iterating on this modular design, this lab has created a series of snake robots over 15 years [20.17, 18]. In

Fig. 20.3a–d Slim Slime (a) and the new generation of ACM-R snake robots: (b) ACM-R3; (c) ACM-R4; (d) ACM-R5 (after [20.1])

Fig. 20.4 Snakey, the snake robot showing also Joel Burdick, Greg Chirikjian, Howie Choset, Jimbo Ostrowski (after [20.8])

addition to the mechanism, one of the major innovations of this work is gaits, the controllers that prescribe motion for the snake robots. These gaits generalized the gait motion, based on Hirose's serpenoid curve and Chirikjian's modal functions, to perform a large variety of behaviors including climbing up poles, swimming in a pond, maneuvering through pipes, and breaching through a fence [20.19]. Working with Robin Murphy's group at Texas A&M, the snake robots have been fine tuned for urban search and rescue use. This created an ideal platform for infrastructure inspection such as networks of pipes in power plants. In 2012, Choset sent his robots to Egypt for archaeology in confined spaces [20.20].

In Norway, Øyvind Stavdahl in the Gemini Centre for Advanced Robotics created several snake robots, many of which were in collaboration with the Norwegian University of Science and Technology. The first of these major research projects in snake robotics was the Anna Konda (2005-present), a firefighting snake concept. Based on hydraulic actuation, this robot is powered entirely by the pressure of a fire hose, and is designed to reach flames in areas that are either too dangerous or too small for firefighters to reach [20.21].

This team also created AIKO (2006–2010), a snake robot created to experiment with snake locomotion that could later be applied to Anna Konda [20.22]. Mostly focused on object-aided locomotion, AIKO evolved

into KULKO (2010–present), a robot with a force-sensing body that uses its simple understanding of the obstacles it is in contact with in order to locomote more effectively. These two robots have produced several innovative movement algorithms for object aided locomotion that could be applied to Anna Konda as well as other nonwheeled snake robots [20.23].

The snake robots described above rely on internal motions to propel themselves forward. *Johann Borenstein* at the University of Michigan created the Omni-Tread (2004) robot [20.24] that propels itself with moving threads situated along side of the robot. Its strong joints are actuated by pneumatic bellows. The bellows can be proportionally controlled, allowing its body to be fully compliant while crossing rubble to have more of its body touching the ground, or strong enough to lift half of its body weight, which is necessary for ledges and gaps. The Omni-Tread excelled at moving over rubble [20.24].

David Anhalt and James McKenna at SAIC took the tread concept to the limit; they designed and built a toroidal skin drive, a drive mechanism that has reciprocating skin that consists of an elongated toroidal skin that covers the entire length of the robot, and a drive unit which propels it. The outer (tubular) layer of the skin slides axially from the head to the tail of the snake robot, and wraps inside itself over a captured ring at the tail. The skin then recirculates from the tail to the head (through the center of the outer tubular layer), and changes direction again (over a second captured ring at the head) to again become the outside layer. In this configuration, the skin forms a continuous toroidal loop. The SAIC team collaborated with Choset's group to build a snake robot using this drive mechanism [20.25].

Finally, we describe some snake robots that use wheels to locomote. Hisashi Date, who heads a research team at the Robotics Lab for National Defense Academy of Japan, built a snake robot in 2007 to trace lines using lateral undulations and a line-tracing sensor arm. Date later developed in 2009 a mechanism that has passive wheels; it is very similar to Shigeo Hirose's first ACM robots, except it is powered by hydraulics. Date's robot also implements touch sensing much like being planned for Anna Konda [20.26].

Fig. 20.5 (a) Yim's original Polypod robot (after [20.10]) and (b) current CK Robot in a wheeled snake configuration (after [20.13])

Fig. 20.6 Choset's Modsnake consisting of 16 DOFs (degree of freedom) each orthogonally placed with respect to each other (after [20.17, 18])

Fig. 20.7 Anna Konda snake robot (after [20.21])

Another wheeled snake robot is HAUBOT (2009-present), developed by Akio Ishiguro at Tohoku University. It is being used to study the autonomous decentralized control mechanisms underlying the adaptive locomotion of animals. It uses real-time tunable rubber springs to actuate each joint. Each joint generates

torque proportional to the difference between the joint angle and the target angle which is given by the anterior joint angle. By using just this method of simple sensing, the robot can locomote in two dimensions, without requiring a centralized control hub. More recently, HAUBOT has been successfully paired with head tracking software so that it can be driven intuitively [20.27].

At Kyoto University, Fumitoshi Matsuno has also developed several snake robots. Matsuno has made many innovations in the control of snakes with different modes of propulsion. In 2002, Matsuno and his lab built KOHGA, a treaded snake robot made for search and rescue. Its joints can be passive or active, allowing it to move through rough terrain and also lift parts of its body [20.28]. Another robot they have developed is a snake robot that propels itself using screw-inspired modules. Built in 2010, it uses many of the same control algorithms as KOHGA except besides moving forward, backward, and turning, it can also roll sideways perpendicular to its head direction [20.29].

These labs together have created an incredible variety of snake-like robot locomotion. Snake robots can now traverse nonflat fields, climb poles, swim underwater, and even rebuild themselves. They can access incredibly small spaces and transition between swimming to slithering to climbing without having to be reconfigured. Advancing far beyond slithering across flat ground, these robots are nearly ready to begin tackling spaces in the field that no other robot can reach.

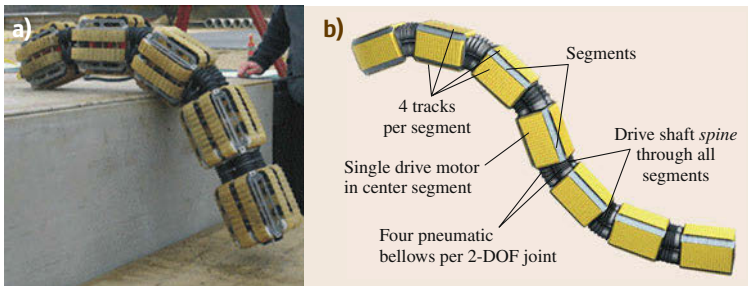

Fig. 20.8a,b The Omni-Tread treaded snake robot (a) and an (b) illustration of its design (after [20.24])

Fig. 20.9 The SAIC skin drive mechanism followed by the SAIC/CMU snake robot powered by the skin drive mechanism (after [20.25])

Soon these robots may be found in the pipes of oil refineries, crawling through nuclear power plants, at the

front line of search and rescue operations, fighting fires or exploring underwater environments.

20.2 Continuum Robots – Short History

The term *continuum manipulator*, first coined by Robinson and Davies in [20.30], which is equivalent to the *continuous morphology manipulator* defined in [20.31], indicates the snake/hyper-redundant robot concept taken to the extreme. In other words, conceptually this category of robots have backbone structures *taken to the limit*, with their number of *joints* tending to infinity, but with their *link lengths* tending to zero, which is also the approach taken in Chirikjian and Burdick's work on backbone curves. While this concept initially appears idealistic, complicated and impossible to implement, the limiting case (a smooth *continuum* curve, with the ability to bend at any point along the backbone) is quite easy to realize in hardware.

Numerous continuum designs have been proposed since the early 1960s beginning with the *Tensor Arm* [20.32] developed based on the original *Orm* concept of Leifer and Scheinman [20.33]. With a flexible backbone bent by remotely driven tendons, the Tensor Arm anticipated numerous later designs. However – a key issue with later continuum robot designs until the 1990s – coordination of the inputs to take advantage of the shapes achievable by the robot proved difficult. This lack of enabling underlying models for motion planning (now much less of an issue, see the following section) hindered the development of the field for many years.

Nevertheless, some researchers, beginning with *Shigeo Hirose* [20.2], continued to explore the problem of constructing continuum robots. Many of these efforts were inspired by an evolving knowledge of the morphology and functionality of biological continuum structures [20.34–36] particularly the trunks of elephants [20.37–39] and the arms of octopuses [20.40–42]. The key robot design issues revolve around how to actuate (bend and possibly extend/contract) the backbone. Two basic design strategies have emerged [20.43, 44]: (1) extrinsic actuation, where the actuators are separate from the backbone structure, e.g., [20.45–49]; and (2) intrinsic actuation, where the actuators represent a fundamental part of the backbone, e.g., [20.50–53].

Extrinsically actuated designs have the advantage that by locating the actuators outside the robot workspace, the backbone itself can be simplified and streamlined. Tendons have proved a popular and generally successful choice for extrinsically actuated continuum designs [20.38, 54, 55]. Groups of tendons are terminated at specific points down the backbone, and

combine to bend the backbone to produce a series of (usually constant curvature) *sections*. The tendons bend a backbone that is nominally straight (realized either via an elastic rod [20.56], the incorporation of springs [20.38], or pneumatic chambers [20.57, 58]). A good example of the ability of this design strategy to produce a long, thin backbone with extrinsic actuation is given by NASA Johnson Space Center's *Tendrill* ([20.49], Fig. 20.10), intended to penetrate through small orifices and explore in tight spaces for Space applications.

In recent years, a completely different form of extrinsically actuated continuum robot, based on concentric tubes, has appeared. These concentric tube [20.59, 60] (sometimes termed as active cannula [20.61]) robots have been primarily motivated by medical applications [20.62]. Research has focused on application (e.g., as active endoscopes [20.63–66]) within the human body [20.67, 68], on various types of minimally invasive surgical procedures [20.69–71], and the associated development of *steerable needle* technologies [20.72–74].

Concentric tube robots, as the name suggests, form the robot backbone from several (typically two or three) hollow tubes, with tubes of smaller radius inserted through those of larger radius. Each smaller tube can be pushed through the tube immediately outside it to extend the backbone length. The tubes can also be rotated, to give $2n$ degrees of freedom for an n -tube backbone. The tubes are preformed to have a constant curvature, so can be extended and bent (albeit with amount

Fig. 20.10 NASA's *Tendrill*, an extrinsically actuated continuum manipulator (after [20.49])

Fig. 20.11 Externally actuated concentric tube continuum manipulators

Fig. 20.12 The OC Robotics Snake-Arm robot – an externally actuated *continuum-like* robot with segmented backbone (after [20.75])

Fig. 20.13 The intrinsically actuated *Octarm* pneumatic continuum manipulator and its development team (after [20.42])

of bending preset) in arbitrary directions (Fig. 20.11). This design arrangement is well-suited to the medical applications which have motivated its development. Numerous prototypes have been developed in the last several years, and the results of initial trials are highly promising. This work is being pioneered by the groups of *Pierre Dupont* at Boston University [20.59, 73, 74,

76], *Michael Zinn* et al. at the University of Wisconsin [20.62, 77], and *Robert Webster, III* et al., at Vanderbilt University [20.44, 61, 67, 78].

Note that the backbone for extrinsically actuated robots does not have to be continuous to produce the continuum effect [20.47, 79, 80]. A commercially successful group of extrinsically actuated continuum-like *snake-arm* manipulators are currently manufactured and retailed by OC Robotics (OCR) in the United Kingdom [20.75]. Remotely tendon-driven (designed by Rob Buckingham and Andy Graham of OCR), but with a snake-like segmented backbone (the number and form of segments can be changed) these snake-arms give a continuous backbone effect. OCR's manipulators (Fig. 20.12) are currently the only general purpose continuum-like robot commercially available, and have been deployed in nuclear reactors and inside airframes, among other applications for largely noncontact operations in tight, cluttered spaces. This ability to penetrate and *slither through* complex environments (mirroring NASA's goals for *Tendrill*) is one of the main motivations and anticipated practical advantages of continuum robots.

Intrinsically actuated continuum robots have their actuators within the continuum backbone. Indeed, the backbones of most intrinsically actuated continuum robots are largely formed by their actuators. Artificial muscle technologies, notably pneumatic McKibben muscles, have proved most effective in intrinsically actuated hardware realizations [20.50, 81]. A particular advantage of intrinsic actuation is the ability to produce extensible backbones [20.43, 44].

For example, Ian Walker's group at Clemson led the development of the octopus-arm inspired *Octarm* intrinsically actuated extensible continuum manipulators ([20.42], Fig. 20.13, [VIDEO 158](#)). The backbone of the *Octarm* is formed from its actuators: sets of (3) McKibben muscles arranged in series to give three or four sections. Several generations of *Octarm* were tested in field trials, mounted on a Foster-Miller Talon mobile base [20.81] ([VIDEO 157](#)). The robots were shown to be able to grasp and manipulate objects over a wide range (order of magnitude) of sizes and weights, and of widely varying shapes and textures [20.82]. This

Fig. 20.14 The intrinsically actuated bionic handling assistant by *Festo* (after [20.50])

ability to adapt shape to perform *whole-arm manipulation* [20.83] with the backbone is another prime motivation for continuum robots [20.84].

Another good example of an intrinsically actuated continuum robot is the Bionic Handling Assistant recently developed by Festo [20.50] (Fig. 20.14). This continuum robot is unusual in that it is preshaped for its sections to be nonconstant curvature. The curvature is biologically inspired.

Currently, another biologically inspired (once again by the octopus) large project, under EU funding, led by Darwin Caldwell, and featuring researchers in Greece, Israel, Italy, Switzerland, and the UK, is working toward creation of a *European Octopus* robot [20.40, 85] (Fig. 20.15). This robot features multiple continuum limbs [20.85]. The European group has considered both intrinsic [20.86] and extrinsic actuation [20.40] for their limbs.

Many snakelike/continuum robotic devices have found applications in the medical area. This includes very flexible steerable needles [20.87–91], and the

Fig. 20.15 The *European Octopus* continuum-limbed robot (after [20.40]) (currently under development)

concentric-tube robots mentioned earlier [20.73, 74, 92–97]. Other recent medical snake robots include novel articulated designs [20.98, 99], and stiff-continuum-filament cable-driven designs [20.100–103].

20.3 Snake-Like and Continuum Robot Modeling

While continuum manipulators are seen to be the extreme case of snake-like or hyper-redundant structures, it was quickly realized that they represent a fundamentally new class of manipulators [20.43, 44, 104]. A continuous flexible backbone features, at least in theory, an infinite number of degrees of freedom. As such, the traditional tools in robotics for modeling (a finite number of) serial rigid links no longer apply. Additionally, it is obviously not possible to actuate an infinite number of degrees of freedom in practice. Continuum manipulator hardware universally features a finite number of actuators, applying forces/torques to the backbone at a fixed and preselected set of locations. This causes significant complexity in their analysis. However, significant progress has been made, and understanding resulting from analysis of continuum kinematics has been applied, as discussed in the following section.

Clearly, to correctly model continuum manipulators, models based on continuous backbones are required. Interestingly, such models have also proved to be key theoretical resources in the motion planning of rigid-link hyper-redundant systems. While in theory discrete-link hyper-redundant manipulators can be modeled (and their planning based on) traditional manipulator modeling techniques, it was quickly found that the computational complexity of such approaches made them difficult to implement, and the correspond-

ing models hard to visualize. An alternative strategy (and a more successful one in practice) has been to adopt an approach based on continuum manipulator kinematics. In the following, we overview the recent development of continuum manipulator kinematics. We then discuss how the existence of both discrete-link and continuum models have enhanced motion planning for each category of hyper-redundant system.

The lack of distinct links in continuum systems makes the standard robot manipulator modeling strategy of a finite number of coordinate frames (each fixed in one link) inappropriate for their modeling. Instead, the natural approach is to model continuum kinematics via a frame which evolves along a continuous backbone, parameterized by arc length s . Local motion of the backbone at point s is modeled in terms of the local frame at s . This strategy allows computation of *forward kinematics*, and construction of *continuum Jacobians*, analogous to those for rigid-link systems [20.31, 105].

Numerous alternatives for selection of the backbone frames have been proposed [20.31, 106–109]. In all such approaches, positions along the backbone curve can be expressed relative to the unit tangent, $u(s)$, as

$$x(t) = \int_0^t [1 + \varepsilon(s)] u(s) ds.$$

In this formulation, $\varepsilon(s)$ is the local extensibility, or stretch, of the curve. If this quantity is equal to zero, then t becomes arc length. Otherwise, equal increments of t can correspond to different lengths along the curve, with a positive value of $\varepsilon(s)$ corresponding to a stretch, and negative values corresponding to a compression. While most continuum robots have a backbone that is essentially inextensible, the reason for introducing this variability is that allowing certain sections to stretch or compress affords greater freedom to hyper-redundant manipulators with discrete stages, making it easier to *fit* the physical robot to the curve. This fitting process takes as an input not only the relative positions of the distal and proximal ends of each stage, but also orientations. If the tangent is taken as one of the axes of a reference frame, a choice for the other two axes remains and can be made in a number of different ways. Once this choice is made, a reference frame

$$g(t) = (R(t), x(t))$$

is established at each value of t and relative rigid-body displacements are computed for stages as

$$\begin{aligned} & [g(t_i)]^{-1} \circ g(t_{i+1}) \\ &= ([R(t_i)]^T R(t_{i+1}), [R(t_i)]^T (x(t_{i+1}) - x(t_i))) . \end{aligned}$$

In the inextensible case where the curve parameter becomes arclength s one natural choice for defining the orientation $R(t)$ is the well-known Serret–Frenet frame [20.31, 108, 109] which evolves along the backbone according to the following

$$\begin{aligned} dt/ds &= \kappa n \\ dn/ds &= -\kappa t + \tau b \\ db/ds &= -\tau n . \end{aligned}$$

In the above, the frame origin is given by x , where the unit tangent to the curve $t = dx/ds$ (denoted as t rather than u), and forms one of the frame axes. The other axes are defined as the normal ($t \cdot n = 0$) and the binormal $b = t \times n$. The curvature κ and torsion τ dictate the shape of the curve. The axes of the Frenet–Serret frame provide an intuitive visualization of local movement: two possible dimensions of bending, corresponding to rotations about the normal and binormal axes, and one of extension/contraction (present and controllable in several continuum robots), corresponding to translation along the tangent axis.

The Frenet–Serret model has the advantage of being a well-established means for modeling continuous spatial curves. The drawback of this formulation is that it is not *optimal* in the sense that for a given curve

shape, the total amount of motion of the evolving reference frame required to traverse the curve is not minimal subject to end constraints and the requirement that one axis of the reference frame is the tangent. Variational calculus can be used to obtain the optimal framing of curves, as reviewed in [20.31] in the context of coordinate-dependent optimization, and in [20.110] using a coordinate-free approach.

Moreover, there are multiple approaches to defining the evolution of the tangent, and hence the shape of the curve. Consider an inextensible curve whose shape has not yet been specified, and let the unit tangent to the curve be defined relative to an a priori-unknown arclength-dependent orientation as

$$u(s) = R(s)e_3 .$$

The goal is to find $R(s)$ such that the positional constraint

$$x(L) = \int_0^L u(s) ds ,$$

and the orientational constraints on $R(L)$ are satisfied when $R(0) = I$. Here, I is the identity matrix and the manipulator has length L .

Treating s as time, then corresponding to $R(s)$ is an angular velocity $\omega = (R^T dR/ds)^V$, where the V operation extracts the dual vector of a skew-symmetric matrix. We can then ask what $R(s)$ is optimal in the sense of minimizing a cost of the form

$$I = \frac{1}{2} \int_0^L [\omega(s) - b]^T B [\omega(s) - b] ds .$$

When $b = 0$ and B is the moment of inertia of a cross section of the manipulator, this is akin to kinetic energy of rotation, and minimizing it provides an evolution of reference frames that minimally rotate. Variational calculus provides the conditions

$$B\dot{\omega} + \omega \times (B\omega - b) = \begin{pmatrix} -\lambda^T R e_2 \\ \lambda^T R e_1 \\ 0 \end{pmatrix} ,$$

that can be integrated numerically and the rotation matrix $R(s)$ is obtained from the angular velocities by integrating

$$\dot{R} = R \left[\sum_{i=1}^3 \omega_i(s) E_i \right] ,$$

where

$$E_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix},$$

$$E_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix},$$

$$E_3 = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The three-dimensional vector of Lagrange multipliers λ and the a priori unspecified initial value of the three-dimensional vector ω at $s = 0$ together provide six degrees of freedom with which to match the end constraints on position and orientation. In this way, curves of fixed length that vary in shape as little as possible while meeting end constraints can be generated.

Alternative frame representations in the continuum robot literature also have selected the axes of the frame to align with the controlled motion axes of particular hardware realizations [20.47, 107]. In either case, given a frame, the key problem is how to use the resulting model to plan motions. The basic issue is that the continuum kinematics models in their basic form feature infinite degrees of freedom (as necessary to model arbitrary spatial curves). However, hyper-redundant robots (discrete-joint or continuum) can be controlled in only a finite number of ways, thus admitting a reduced set of physical solutions. Therefore, research in continuum manipulators has concentrated on how to constrain continuum kinematics models to best represent robot hardware.

The initial major breakthrough in motion planning for hyper-redundant arms was made in a landmark series of publications by Chirikjian and Burdick [20.31, 105, 111] introducing continuum kinematics and using them to approximate rigid-link hyper-redundant systems [20.105]. Basically, the philosophy is to use a (theoretical) curve to model the physical backbone of a hyper-redundant robot. Motion planning is performed for the curve, and the (discrete) robot backbone then *fit* to the resulting (continuous) solution curve. This approach has proved quite effective, and the associated research introduced several key theoretical concepts to the area. In particular, the use of a modal approach [20.105, 112] (restricting the classes of allowable solutions to shapes generated via simple

linear combinations of *modes*), arose from this approach to redundancy resolution for hyper-redundant manipulators. This concept can be viewed as a *top-down* approach of building a general model, and adapting it (via mode selection and curve-fitting) to hardware.

In the planar case, the angle of the rotation matrix $R(s)$ is simply the integral of the curvature of the curve. Expressing this curvature as a weighted sum of two functions, or modes, then restricts the manipulator to act as if it only has two degrees of freedom. As an example of this modal approach, a closed form solution can be obtained for inextensible manipulators of unit length by restricting the curvature to be a linear combination of $\cos 2\pi s$ and $\sin 2\pi s$. If the coefficients in front of these functions are, respectively, $2\pi a_1$ and $2\pi a_2$, then

$$x_{ee} = \sin(a_2)J_0 \left[(a_1^2 + a_2^2)^{\frac{1}{2}} \right],$$

$$y_{ee} = \cos(a_2)J_0 \left[(a_1^2 + a_2^2)^{\frac{1}{2}} \right],$$

where J_0 is the zeroth-order Bessel function.

And inverse kinematics can be achieved in closed form by computing

$$\begin{aligned} a_1 &= \hat{a}_1^\pm(\bar{x}_{ee}) \\ &= \pm \left(\left\{ J_0^{-1} \left[(x_{ee}^2 + y_{ee}^2)^{\frac{1}{2}} \right] \right\}^2 \right. \\ &\quad \left. - [\text{Atan2}(x_{ee}, y_{ee})]^2 \right)^{\frac{1}{2}} \end{aligned}$$

$$a_2 = \hat{a}_2(\bar{x}_{ee}) = \text{Atan2}(x_{ee}, y_{ee}).$$

In this planar example the convention that the tangent to the curve at the base of the manipulator points along the y axis has been used.

This closed-form solution has also been used to generate closed-form solutions for spatial manipulators, as well as to define waves that travel along the manipulator for the purpose of obstacle avoidance, locomotion and manipulation. This is illustrated in Figs. 20.16–20.18 [20.31] with a variable-geometry truss superimposed on the backbone curve. In the context of obstacle avoidance, the modal solution given above is scaled in order that the part of the manipulator outside of the obstacle field terminates at a position to allow entry, and the section inside of the obstacle field has curvature that is piecewise constant to maneuver around the obstacles.

In the context of locomotion, the modal approach is used to ensure that the end conditions on a traveling wave match those of terrain. In the context of grasping

and manipulation, the modal approach is used in two ways. First, it defines the shape of a locomotion-like traveling wave that traverses the grasped object. This extends the reach of the manipulator around the object. Then, the bottom part of the manipulator contracts to form a shape defined by the modes while the part of the manipulator that is closest to the base yet in contact with

Fig.20.16a–d Using the modal approach to position part of a manipulator at the entry of an obstacle field (after [20.31])

Fig. 20.17 Net motion to the left by wave propagation (after [20.31])

the grasped object unwinds. The result is a combination of waves and unwinding that produce net rotation of grasped objects without ever letting go, as described in [20.31, 113].

More recent research has concentrated on the notion *dual* to that of the previous section, using the physical constraints imposed on the backbones of specific continuum robot hardware types to construct continuum kinematics. This can be viewed as a *bottom-up* approach, focused on particular hardware classes, with the main aim of sufficiently modeling the hardware to avoid the use of approximations in the motion planning. Examples of this approach are given in [20.44, 107] where the key constraint imposed on a general continuum kinematics model arises from the observation that many continuum hardware implementations resolve into a finite number of constant curvature sections. (This arises naturally from the imposition of a finite number of input force/torques on a stiff continuum backbone). In [20.106], it is noted that the resulting constant curvature models can be viewed as a particular case of the general modal approach of [20.105].

The approach shown [20.44, 107] involves several transformations [20.114], to transition the map between task and actuator space via a *section* space. As key part of this transformation, a conventional (theoretical) rigid-link model can be used to model the kinematics of each section. Thus, rigid-link kinematics have proven key to resolving redundancy for continuum manipulators, as continuum kinematics play a key part in redundancy resolution for rigid-link hyperredundant arms.

Finally, a series of Jacobians are formed. The difference here is that the continuum Jacobian is a function of locally meaningful variables (bending angle, curvature, and extension) defining section shape or the direct values of actuators which determine these variables. Given the existence of continuum Jacobians, the redundancy is usually resolved as

$$\dot{\mathbf{i}} = J_E^\dagger \dot{\mathbf{i}}_E + \left(I - J_E^\dagger J_E \right) \dot{\mathbf{i}}_0$$

in the same way as for conventional redundant manipulators (and with the same general corresponding advantages and issues), as discussed in Chap. 10.

Recent efforts have extended the progress in continuum robot kinematics to develop dynamic models for continuum robots [20.84, 104]. New models based on the Lagrangian [20.108, 115] and Newton–Euler [20.116] formulations have been introduced. Progress is impeded by the complexity of the dynamics of continuous backbones with large deformations, and many models remain too complex for practical

Fig. 20.18 Net rotation of an object by wave initiation at base and wave propagation (after [20.31]) ►

implementation. Hence, recent work has focused on implementable dynamic models based on simple, lumped-parameter models [20.117].

The new kinematic and dynamic models are in turn now enabling research in continuum robot motion planning [20.118, 119] and control [20.120, 121]. New models for force estimation [20.122], handling [20.76, 123], and sensing [20.124] using continuum robots have been introduced. Both model-based [20.54] and non-model based [20.125] controllers have been proposed. Controllers have been proposed in both configuration and task [20.54, 126] space. However, at this time, implementation of model-based controllers is rare.

20.4 Modeling of Locomotion for Snake-Like and Continuum Mechanisms

Snake and continuum robots have the ability to use their entire bodies to interact with the environment in order to produce purposeful motion [20.127–136]. Locomotion is a challenging motion planning and control problem because a planner/controller must contend with many degrees of freedom at once, even if they were somehow reduced with approaches like the backbone method, discussed above. Many researchers achieve this by modeling the snake robot's motion with a *gait*, a cyclic motion in the internal degrees of freedom of a mechanism that produces net motion. It makes sense to implement gaits because all locomoting animals exhibit gaits: horses gallop, trot, and walk; snakes sidewind, laterally undulate, and linearly progress.

The benefit of the gait is that one can reduce a complex system down to a few set of parameters that describe the gait and then by cycling through the phase of the gait, a planner can achieve locomotion. So, if the gait were just a sinusoid, the user specifies amplitude, frequency, and phase and the mechanism is then *fit* to the sinusoid, which requires very little computation as was seen with the backbone method. To achieve motion in three dimensions, we describe gaits for the snake robot with two sinusoidal waves lying in two mutually perpendicular planes, a horizontal plane parallel to the ground and a vertical plane perpendicular to the ground. Recall that some of the mechanisms, described above, consists of single degree of freedom joints, each placed orthogonally to its neighboring joints. For the sake of notation, we ascribe the even joints to modules that bend in the vertical plane and odd joints to modules that bend in the horizontal plane. So, if a vertical wave

perpendicular to the ground is sent through the mechanism, only the even modules participate, while the odd modules remain stationary. Likewise, only the odd modules participate in sending lateral waves parallel to the ground through the robot. Should the snake robot fall onto its side, then even modules simply become the lateral modules and the odd become the vertical modules.

Given that the even modules are responsible for propagating vertical waves and the odd for propagating lateral waves, we use the terms $\text{offset}_{\text{vertical}}$, $\text{offset}_{\text{lateral}}$, $\text{amplitude}_{\text{vertical}}$, and $\text{amplitude}_{\text{ground}}$ to denote the parameters affecting the two orthogonal waves. Finally, we assume that both offset parameters are set to zero, unless otherwise noted. All of our differentiable gaits can be described by an angle of the n -th module at time t as

$$\begin{aligned} \text{angle}(n, t) &= \begin{cases} \text{offset}_{\text{even}} + \text{amplitude}_{\text{even}} * \sin(\theta), & n = \text{even}, \\ \text{offset}_{\text{odd}} + \text{amplitude}_{\text{odd}} * \sin(\theta + \delta), & n = \text{odd}, \end{cases} \\ \theta &= \left(\frac{d\theta}{dn} * n + \frac{d\theta}{dt} * t \right). \end{aligned} \quad (20.1)$$

The offset is generally used to aim the robot when locomoting on the ground. For instance, when the snake is straight or climbing a pipe, the offset is zero. The am-

plitude terms describe the amplitudes of the mutually perpendicular waves. In most cases, the amplitude and speed of the robot are directly correlated and as both increase, the robot can better reach over large obstacles. However, larger amplitude comes at the cost of reduced stability. Intuitively, given a fixed number of modules, the fewer waves in the robot, the larger each wave can be. Thus, smaller values of $d\theta/dn$ allow more modules to participate in any one wave, which in turn allows for larger waves.

The frequency of the sine wave is determined by θ , which increases with time and along the length of the snake robot. The rate at which θ changes is controlled by the $d\theta/dn$ and $d\theta/dt$ terms. Note that the sine wave moving through the robot has a spatial and temporal component: 1) $d\theta/dn$ determines the spatial component, meaning if we freeze time (fix t), it tells us what the robot as a whole looks like, and 2) $d\theta/dt$ determines the frequency of the temporal component,

meaning that if we examine the sinusoidal trajectory of one individual actuator (fix n), we determine how it moves. A zero value for $d\theta/dn$ causes identical angles on all of the modules on one axis, generating an arc along that axis, and a zero value for $d\theta/dt$ has the effect of freezing time. Finally, δ is simply an offset to control the timing between the motions of the two orthogonal waves. These parameters can be modified to change the type of and nature of the gait performed by the robot.

Current work includes combining the gait-equation-based approach with backbone curves. We are developing techniques that take an animated sequence of backbone curves and infer the gait parameters from that sequence. The backbone curve approach is easy to visualize and therefore geometrically manipulate. The benefit of the gait approach is that it contains an analytic expression which permits evaluation, and hence optimization. With this new current approach, we can obtain the best of both worlds.

20.5 Conclusion and Extensions to Related Areas

The field of snake-like and continuum robots has blossomed over the past 40 years. The work has taken many different directions including novel designs for locomotion, manipulation, and medical applications, as well as different avenues for applying the resulting modeling techniques including nonholonomic planning and the conformational flexibility and statistical mechanics of biological macromolecules.

It is worth noting that other related works in nonrobotic fields and application areas have developed either in parallel or as a consequence of the efforts mentioned before. For example, continuum

devices were developed essentially outside the field of robotics in [20.137, 138] from the perspective of mechanics. Continuum curve approaches applied to variable-geometry trusses were developed in [20.139–141], essentially in parallel with [20.9]. In recent work, wormlike robots [20.142] have been designed that execute peristaltic waves, motivated by biology akin to those described in [20.113]. Finally, analysis for understanding curves and workspace formulations for snake and continuum robots have been used to study deoxyribonucleic acid (DNA) [20.110, 143–148].

21. Actuators for Soft Robotics

Alin Albu-Schäffer, Antonio Bicchi

Although we do not know as yet how robots of the future will look like exactly, most of us are sure that they will not resemble the heavy, bulky, rigid machines dangerously moving around in old-fashioned industrial automation. There is a growing consensus, in the research community as well as in expectations from the public, that robots of the next generation will be physically compliant and adaptable machines, closely interacting with humans and moving safely, smoothly and efficiently – in other terms, robots will be *soft*.

This chapter discusses the design, modeling and control of actuators for the new generation of soft robots, which can replace conventional actuators in applications where rigidity is not the first and foremost concern in performance. The chapter focuses on the technology, modeling, and control of *lumped parameters* of soft robotics, that is, systems of discrete, interconnected, and compliant elements. *Distributed parameters*, snake-like and continuum soft robotics, are presented in Chap. 20, while Chap. 23 discusses in detail the biomimetic motivations that are often behind soft robotics.

The chapter starts by analyzing the main motivations that are behind the development of actuators for soft robotics: these are mainly safety of operation, especially in interaction with humans; resilience of the robot itself in interaction with harsh, unpredictable environments, and performance enhancement in dynamic tasks.

We then briefly survey the different principles and technologies that can be used to implement actuators for soft robotics. Using natural muscles as a term of comparison, we consider different elements constituting an actuator, such as the prime movers, energy storage and dissipation elements, and their different possible arrangements.

We then move to consider a class of actuators for soft robotics that includes many of the recent developments in this field, that is, the class of variable

impedance actuators (VIA) and the subclass of variable stiffness actuators (VSAs), and consider how a mathematical model of these systems can be provided in general but precise terms. With the objective of helping the reader navigate the space of the many existing, and many more conceivable, designs we consider these actuators from a general point of view, discussing how their performance envelope and specifications could be given in a unified, comprehensive way.

In the final part of the chapter, we consider the new problems and opportunities arising from the control of soft robots, including the need to estimate the variable physical compliance of the actuators, to plan its variations to adapt to tasks and environments, and to do real-time control of soft robots exploiting their physical properties.

21.1 Background

21.1.1 Motivations

The intrinsic properties of the biological muscles and their advantageous arrangement within the musculoskeletal system are a key aspect to the motion performance of many animal species. The flexibility, force-to-weight ratio, viscous damping, and fast reacting properties provide animals with an actuator having properties well suited for the tasks they are faced with day to day. Taking the human as an example, our muscles allow us to do very fine manipulation, precisely exerting forces and torques at the millinewton level, but also lift objects at a 10 : 1 force-to-weight ratio. Through the interplay of these physical properties with the neural sensory-motor control, motion is accomplished in a very energy-efficient, safe, and effective way.

Despite the diverse range of actuation techniques developed over the past years, the lack of an actuator which can reach the functional performance of the biological muscle and its neuro-mechanical control system still remains one of the most significant barriers for the development of machines, which can match the motion capabilities of natural systems. This observation has motivated many researchers in recent years to work to-

ward developing and exploiting actuation technologies for a new generation of soft robots, which can co-exist and co-operate with people and reach or even surpass their performance.

21.1.2 Safety

One of the main motivations for revisiting traditional robotic design is the concern about their safety: it is to be expected that interacting with robot assistants or collaborators should not constitute (or even just be perceived as) a higher injury risk to humans than the interaction with another cautious human. Attention toward safe operation of robots near to, and even in contact with, humans is rather recent, although some of the pioneering contributions date back to the 1990s [21.1]. Robot-specific risk assessment methods have been studied in recent years [21.2, 3], and are discussed in Chap. 69.

The inherent danger to humans of conventional arms can be mitigated by retro-fitting their design by increasing their sensorization (using, e.g., proximity-sensitive skins), or by increasing the energy-absorbing properties of protective layers (adding enough soft and compliant coverings or placing airbags around the arm).

Starting in the early 1990s, researchers have gradually abandoned the retro-fitting approach and started designing robots with interaction safety in mind from the beginning: notable examples are MIT's **WAM** (whole arm manipulator) [21.4] and DLR's **LWR** (light-weight robot) [21.5]. Arms in this class are primarily characterized by low inertia of their moving parts (links and motors) and backdrivability. Advanced sensing and control can realize a *soft* behavior via software.

Another approach to increase the safety level of robot arms interacting with humans is *soft robotics*, that is, to intentionally introduce mechanical compliance and damping in design. By this researchers tend to replace the sensor-based computation of a behavior and its error-prone realization using active actuator control, by its direct physical embodiment, as in the natural example. Having compliance and damping in the robot structure is by no means sufficient to ensure its safety, as it might indeed be even counterproductive for the elastic energy potentially stored. Just like a human arm, a soft robot arm will need intelligent control to make it behave softly as when caressing a baby, or strongly as when punching.

21.1.3 Resilience

Physical interaction of a robot with its environment can also be dangerous to the robot itself. Indeed, while fortunately the number of accidents involving robots and humans is very limited, the number of times a robot is damaged because of impacts or force overexertion is rather large, and clearly the more so the less structured is the task and/or the environment. A typical cause of breakdown for traditional robots is the failure of reduction gears (especially harmonic drives are quite sensitive to shock loads) and motor bearings, but large accelerations can easily damage sensors and electronics. Although seldom considered in the scientific literature, resilience to shocks is not only instrumental to achieve viable applications of robots in everyday life, but would also be very useful in industrial environments, substantially enlarging the scope of applicability of robot technology. Soft robotics technologies can provide solutions that are extremely effective in absorbing shocks and reducing accelerations: soft materials can be used as coverings or even as structural elements in robot limbs, but the main technological challenge remains with soft actuators and transmissions.

21.1.4 Performance and Energy Efficiency

A further reason to search for a new generation of actuators with controllable compliance is for their dynamic

behavior, which can afford high-performance, natural-looking motion while being more energy-efficient than rigid robots.

Indeed, adaptable compliance can be used to adjust the natural dynamics of the robot in tune with those of its environment, so that the intrinsic physical behavior of the resulting system is close to the desired motion. In these circumstances, actuators would only have to inject and extract energy into and out of the system for small corrective actions, thus reducing energy consumption.

The idea of embodying desirable dynamics in the physical properties of soft robots is of particular importance, for example, in walking/running robots and prostheses: indeed, biomechanical studies reveal that compliance adaptation is important for human walking and running. Although most humanoid robots (such as HRP-4 [21.6, 7] and ASIMO [21.8, 9]) use rigid robotics technologies, soft actuators are more and more often adopted in humanoid robots: pneumatic muscles are used, for example, in [21.10] and [21.11], while several legged systems have appeared that use series-elastic actuators [21.12]. What is probably the first prototype of fully physically compliant humanoid has been recently presented in [21.13].

The fact that natural systems change the compliance of their muscular system depending on the gait and environmental conditions, and even during the different phases of the gait, seems to indicate the potential usefulness of variable impedance actuators (**VIA**) for locomotion – yet, because of the technical and theoretical challenges posed, only early prototypes of bipedal walking systems with variable stiffness actuation have been reported so far [21.14, 15], and no humanoid robot has been reported (to the best of our knowledge) making full use of **VIAs**.

Besides their role in reducing energy consumption in cyclic motions, soft robotics can provide definite performance advantages in many other tasks. One notable class are those tasks where performance is measured in terms of peak velocity reached at the end of an explosive-type motion, such as for example, in throwing, hitting, jumping, kicking, etc. Compliance in the robot structure indeed allows to store elastic energy in a build-up phase, and retribute it in the subsequent explosive phase. Furthermore, it permits us to have joints that, at least for a short time duration, move at a substantially higher velocity than the motor shaft [21.16, 17].

21.1.5 The Third Way of Robotic Control and λ

Novel actuators for soft robotics introduce one further interesting innovation for what concerns their control

philosophy and architecture. Indeed, it can be roughly but fairly said that most existing robotic systems are controlled according to either one of two dominant architectures: position-based controller and torque-based controller. Position-based controllers, which prevail in traditional industrial robotics, are rather closed controller architectures built around an inner servomechanism loop, which basically provide the user with the ability to set joint position references, with very limited access to inner variables such as velocities, gains, or torques. Torque-controlled robots, on the other hand, provide a completely open control architecture, whereby the user can specify the motor currents or joint torques directly as a function of all accessible states. While the position-based control is still by far the most widely used architecture, because it requires less costly sensors, actuators and processors, and is more robust, serviceable, and fool-proof, researchers have always had a preference for the versatility and openness of the torque-based control. The introduction of relatively large physical compliance in soft actuators changes the picture considerably. This is particularly true in VIA systems, where the user is provided with the control of neither the joint positions nor torques di-

rectly. Rather, one can specify the neutral equilibrium position of the joint, and the stiffness (and damping) by which the joint is attracted toward it, when external or inertial loads displace it from such equilibrium. To illustrate the difference, consider building a joint for a fully dynamic task, such as jumping on one leg: while position- or torque-control architectures would hardly be able to do the job (unless using very high-performance components), two relatively slow, low-cost servomotor units connected through springs in agonist-antagonist arrangement can already provide a very effective solution.

It should be noted here that such VIA control model is very similar in philosophy to the λ version of the equilibrium-point hypothesis in human motor control [21.18–20]. According to the equilibrium point hypothesis, movements arise as a consequence of shifts in the equilibrium of the motor system. This equilibrium is dependent upon the interaction of control signals, reflexes, muscle properties and loads, but it is under the control of central arm movement [21.21]. In this sense, soft robotics also provide a very interesting arena for exchanging ideas and insights with the research community in motor neuroscience.

21.2 Soft Robot Design

In this section, we provide a concise presentation of the main elements and technologies that may contribute to the development of novel actuators for soft robotics.

21.2.1 Natural Muscles

For comparison and inspiration, it is natural to consider first the characteristics of natural muscles. A typical muscle consists of many thousands of *muscle fibers* working in parallel, organized in *motor units*, that is, one or several fibers with a motor neuron activating them. A single muscle fiber contains several *myofibrils*, made of *sarcomere* separated by *Z disks*. In a sarcomere, *thin (actin) and thick (myosin) filaments* are arranged in a hexagonal lattice, such that one thick filament interacts with six thin filaments. *Cross-bridges* linking actin and myosin pull toward sacromere center from both ends resulting in muscle shortening. Actin and myosin filaments slide against each other by repeated attachment and detachment of cross-bridges, thus resulting in muscle contraction.

As a consequence of their structure, natural muscles have several mechanical properties which differ from conventional actuators. Muscles (and tendons) have spring-like properties, with stiffness and damping in-

creasing with activation, and are capable of storing and releasing energy, but also of dissipating it. Muscles are equipped with sensors which can provide stretch (e.g., spindles) and force (e.g., Golgi tendon organs) information to the nervous system. Muscle tension increases nonlinearly with activation, and – for fixed activation – depends on both length and velocity. Muscles are most often arranged in antagonistic pairs (such as the bicep and tricep in the elbow) or groups (such as in the shoulder): this fact, together with the nonlinearity of their force–stretch relationship, is used to modulate the effective impedance at the joints.

21.2.2 Breaking Down Artificial Muscle Systems

Even a nonexhaustive but reasonably broad analysis of technologies potentially contributing to the development of novel actuators for soft robotics could not fit this handbook chapter. However, we will attempt here to provide a simple categorization of the subject matter, along whose lines a more complete survey could be organized. To this purpose, we will break down a soft robot system into a network of simpler elements, whose behavior is simpler and more easily described.

Like other systems, a soft actuator is comprised of *storage* elements that keep energy inside the same energetic domain, and of *transducers* that allow a flow of energy from one domain to another. Transducers may dissipate energy via heat production (energy *sinks*), or can instead inject energy inside the system (energy *sources*). Sources can, in turn, be divided into *flow* sources, *effort* sources, and *hybrid*, or *real* sources. A flow source determines the amount of flow (linear or angular velocity, heat flow, volume or mass flow, . . .) going through it, without caring for the effort (force, torque, temperature, pressure, . . .) needed to keep such flow. The converse holds for an effort source. A hybrid source, instead, is a device that offers a generic constraint between the effort/flow pair.

Storage and transducer elements can be connected in different arrangements, which may result in completely different behaviors. **VIA**, an important class of actuators for soft robotics, have the characteristic that their overall behavior can be changed under active control between that of an effort and a flow source.

21.2.3 Sources for Soft Actuators

Technologies used as sources for soft actuators vary broadly in nature and scope. In this section, we limit ourselves to provide a list with comments on the range of applicability, while we refer the reader to specific literature for more detailed analysis: for instance, the author of [21.22] compares several active materials in a volumetrically normalized fashion, including stress (force-generating capability), strain (stroke length), speed of actuation, and power and energy metrics.

21.2.4 Pneumatic and Hydraulic

Pneumatic and hydraulic actuators [21.23, 24] include classical tie-rod or rod-less cylinders and rotary motors. Pneumatic actuators are usually low-impedance effort sources, while hydraulics tend to be high-impedance sources, but compliant behaviors can be actively controlled, or obtained through combination with other elements in the actuator system arrangement.

Of specific interest for soft robotics are the so-called *pneumatic artificial muscles* (**PAMs**), a name used to describe contractile linear-motion engines operated by gas pressure. The actuator's core element is a flexible membrane or shell attached at both ends to fittings along which mechanical power is transferred to a load. As the membrane is inflated, it bulges outward and expands radially, and contracts axially thus exerting a pulling force on its load. The force and

motion thus generated by this type of actuator is typically unidirectional in tension (different from bellows, which work in compression). Pneumatic artificial muscles (**PAM**) became popular in robotics through the work of McKibben, who used braided sleeves around an elastic bladder as an orthotic actuator in the late 1950s [21.25], and have been widely used since then in robotics in various forms [21.26–32].

PAMs have an intrinsically nonlinear characteristic (force decreases with contraction) and, due to gas compressibility, they exhibit a natural low impedance. As they act one way, two **PAM** are needed to generate bidirectional motion in an antagonistic arrangement. By a pressure differential on the two muscles, a net joint torque is applied. On the other hand, due to nonlinearity of the stretch/force characteristic, an increase in the common-mode pressure varies the joint stiffness, while leaving torque unaffected. The above characteristics of **PAMs** are somehow similar to those natural muscles, although many important differences exist. From a practical viewpoint, the main drawbacks of pneumatic muscles are the encumbrance, noise, and slow response related to use of pressurized gas, and their relatively limited energy density.

21.2.5 Electromagnetic and Electrostatic

Electromagnetic motors use Lorentz-type forces acting on electric charges moving in a magnetic field. Examples are solenoids, that is, electromagnetically inductive coils wound around a movable steel or iron slug (the armature) [21.33], and rotating or linear induction motors [21.34]. Electromagnetic sources are typically effort sources, although often they have to be matched to the system impedance through gears, which may transform their behavior substantially. On the other hand, stepper motors, that is, brushless synchronous electric machines that divide a full rotation into a large number of steps, can be considered ideally as position sources. Stepper motors are mainly of three main types, that is, permanent magnet, hybrid synchronous, and variable reluctance steppers.

Electrostatic actuators are based on the attraction and repulsion of electric charges [21.35]. They typically require high-driving voltages at low currents (dual in a sense to electromagnetic motors). Linear electrostatic motors can be realized using comb-drive arrangements. While electrostatic drives at macroscopic scales are impractical due to large voltages, they have excellent potential at micro or nanoscale, where microelectromechanical systems (**MEMSs**) with moving, charged plates are far easier to fabricate than coils and iron cores.

21.2.6 Piezoelectric

The *reverse piezoelectric effect*, that is the production of stress and/or strain in a piezoelectric material when an electric field is applied can also be used for actuating robots. Most used inorganic materials for piezoelectric transducers consist of ceramics with perovskite or tungsten-bronze structures, such as barium titanate (BaTiO_3), lead titanate (PbTiO_3) and lead zirconate titanate ($\text{Pb}[\text{Zr}_x\text{Ti}_{1-x}]\text{O}_3$, $0 < x < 1$), commonly known as lead zirconate titanate (PZT) [21.36], while the direct effect of piezoelectric polymers such as polyvinylidene fluoride (PVDF) is mostly used for sensors.

Elementary piezoelectric actuators are best suited for microscale applications, where they can reach very high accuracy. Piezoelectric motors are sometimes used in resonant mode with rectification mechanisms that transform oscillations in net displacements (e.g., traveling-wave, inch-worm and stick-slip stepping motors). Multilayer (stacks) actuators, piling up several layers (usually thinner than $100\text{ }\mu\text{m}$), are used to increase the actuator stroke, while retaining continuous and reversible operation. Stacked actuators are sometimes used within a mechanical amplifier structures, which can reach millimeter strokes (Fig. 21.1) Amplified piezoelectric stack actuators are commercially available from Dynamic Structures and Materials (Franklin, TN, USA) and Cédrat (Meylan, France). In essence, the compliant mechanism accomplishes a force–displacement tradeoff from input to output at the cost of storing energy within the compliant mechanism. This principle has been used in several mechanisms, such as in [21.37].

Ueda et al. [21.38] envision amplified piezoelectric stack actuators as modular units in a *cellular actuator*, drawing a parallel with muscles in that the overall actuation for a given joint is the sum of a number of discrete actionable units connected by compliant material. In the same way, muscles are composed of individual fibers grouped into motor units whose effects are coupled by elastic tendons. In order to function as modular, muscle-cell like units, the compliant mechanism in the

amplified piezoelectric stacks need to have very aggressive force–displacement tradeoffs while fitting into a compact volumetric envelope. This is accomplished by using a hierarchical set of strain amplifiers, where the output of each stage in the amplification is the input to the subsequent stage. Each stage fits inside the subsequent stage; hence, this is referred to as a *nested* strain amplification mechanism. Schultz and Ueda [21.39, 40] present a framework to describe and specify the geometry of a nested configuration that results in a favorable tradeoff that meets design specifications. The work of Schultz and Ueda [21.41] draws yet another parallel with muscle, the idea that the central nervous system has authority over each motor unit in the muscle and activates each one in an on–off manner. This, in essence makes the control of muscles or muscle-like actuators a switching, rather than analog interface, and circumvents the problem of hysteresis inherent in positioning piezoelectric material with an analog voltage. This actuator type also incorporates this idea of redundancy; a lost motor unit (dead piezoelectric stack) does not result in total failure, but rather a loss of performance.

21.2.7 Electro- and Magneto-Strictive

The electro- and magnetostrictive effects exhibited by some materials, that is, the tendency to change their shape under electric or magnetic fields, can also be exploited to build microscale actuators. Electrostriction differs from piezoelectricity because it is exhibited by all dielectric materials, and is proportional to the square of the polarization (instead of linearly). Reversal of the electric field does not reverse the direction of the deformation. Certain engineered ceramics, such as lead lanthanum zirconate titanate (PLZT) have high-electrostrictive constants and can produce strains of the order of 0.1% at field strengths of the order of 1 MV/m. Electrostrictive actuators are typically structured and used like piezoelectric actuators. Similarly, magnetostrictive materials deform under magnetic fields and in proportion to their magnetostrictive coefficient [21.42]. One of the strongest effects is exhibited by Terfenol-D, with strain of the order of 0.1% in a field of the order of 100 kA/m at room temperature.

The pronounced thermal expansion of some materials (e.g., doped single-crystal silicon or polysilicon) can be used to transform heat in mechanical energy and generate motion at micro scales. Temperature is typically controlled by Joules's effect, or through local heat injection, while mechanical amplification is often introduced with MEMS techniques (e.g., symmetric bent-beam or asymmetric bimorph structures).

Fig. 21.1 Example of an amplified piezo actuator with multilayer stacks

21.2.8 Shape Memory Alloys and Polymers

Macro-scale thermal actuators can otherwise be built using shape memory materials, which include alloys (shape memory alloys, **SMA**) and polymers (shape memory polymers **SMP**). Alloys like copper–zinc–aluminum–nickel, copper–aluminum–nickel, and nickel–titanium (NiTi) alloys [21.43] exhibit shape memory when transitioning from martensitic to austenitic phase (one-way effect) and, under particular conditions, also on the opposite phase change (two-way effect). **SMA** can exhibit up to 8% recoverable strain, and can be formed in virtually any shape. Energy inefficiency, slow response times, and large hysteresis are the main limitations. *Torres-Jara et al.* [21.44] have created an **SMA** muscle-like module in a convenient form factor by combining laser-cut **SMA** sheets with plastic hubs so that the hubs move away from one another when energized. These modules can be connected together in series or parallel to make an overall actuator with the desired properties.

SMPs are relatively new shape memory materials, which can be triggered by temperature but also by electric or magnetic field, light or solution [21.45, 46]. The shape change happens with transitions to glass phase, crystallization, or melting. While mechanical properties of **SMPs** are not yet comparable to **SMAs**, **SMPs** have an enormous potential for their versatility, as they range from stable to biodegradable, from soft to hard, and from elastic to rigid polymers.

21.2.9 Polymeric Actuators

Shape memory polymers represent only an example of viscoelastic materials which can be used for actuation. Very intense research has been pursued in recent years on actuators based on several different phenomena exhibited by polymeric materials [21.47]. Electroactive polymers (**EAPs**) are divided into ionic **EAPs** (based on diffusion of ions and solvents) and electronic **EAPs** (based electronic charging of the material). Ionic **EAPs** include polyelectrolyte gels [21.45, 46], ionic polymer metal composites (**IPMC**, such as Naftion by DuPont), conducting polymers (such as polypyrrole (**PPy**) and polyaniline (**PANi**)). Electronic **EAPs** include piezoelectric [21.48], electrostrictive, and dielectric polymers and elastomers (such as acrylic polymers and silicones [21.49]), and flexoelectric polymers, such as liquid crystal elastomers [21.50].

21.2.10 Carbon Nanotubes

Carbon nanotubes (**CNTs**) have a nonpolymeric macromolecular structure consisting of a graphite

monoatomic sheet rolled to form tubes whose length can be about 1000 times their diameter. **CNT** actuators can be realized by using sheets of single- or multiwalled nanotubes as electrolyte-filled electrodes of a super capacitor [21.51], developing up to 0.75 MPa (cf. 0.3 MPa of the human muscle tissue) at low voltages, though still with limited stroke. A recent breakthrough in **CNT** actuators has been the use of highly ordered aerogel sheets, which allowed fabrication of actuators with giant strokes (ca. 180% actuation along the width) with fast response (5 ms delay) [21.52], which is slightly better than the human muscle. The artificial **CNT** muscle is stronger than steel in one direction, and more flexible than rubber in the other two directions [21.53]. When large strokes will be obtained at low voltages, the potential of **CNT** actuators for the design of artificial muscles is clearly enormous.

21.2.11 Energy Storage

Although energy storage elements in artificial muscles use a variety of materials and structures, due to the need of having mechanical energy readily available in dynamic phases, storage in the form of elastic energy prevails. This can be done by either pressurized gas systems (mainly in connection with hydraulic or pneumatic actuation systems), or by deformation of solid elements, that is, springs. Materials for storing a large amount of elastic energy in a small volume, and with limited losses, include special metal alloys (e.g., medium- and high-carbon steel, beryllium copper, and phosphor bronze). Composite materials, in the three main types available (polymer matrix composites (**PMCs**), metal matrix composites (**MMCs**) and ceramic matrix composites (**CMCs**)) offer a wider versatility in obtaining different stiffness, which depends not only on the constituent materials but also on the fiber design. Advanced needs of soft robotics applications motivate research in using sophisticated materials for energy storage, such as, for example, carbon nanotubes, elastomers, and superelastic materials.

Mechanical energy can also be stored in kinetic form through the use of inertial elements, similar to the kinetic energy recovery system (**KERS**) used in F1 racing cars. However, the mismatch with typical slow speeds of robotic joints introduces the need for gears. Conceptual design of **CVT** (continuous variable transmission)-based **VIA**s have been proposed, although research in this direction is still in its infancy.

21.2.12 Energy Dissipation and Dampers

Energy *sinks*, that is, dissipation systems and dampers, are another important element in the construction of

a soft robot actuator. Indeed, underdamped behaviors are both nonnatural looking and potentially dangerous. Damping can be obtained through real-time control, or directly in hardware via electrical shunting or with mechanical devices. The latter have been extensively applied to a diverse range of cases, from the control of excessive structural response to transient environmental disturbances in civil structures, to automotive suspension systems, and more recently in robotics.

Dampers are often classified as either passive, semi-active or active systems, depending on the amount of external power required to perform its functionality. Dampers can be realized using different operating principles, which we briefly summarize here.

A friction damper (FD) is essentially composed of an actuator that applies a normal force on the output shaft, and generates friction as a consequence of relative motion ([21.54] for modeling). The control of the compression force between the frictional surfaces controls friction and can simulate damping: this has been effectively used in robotics to implement variable physical damping [21.55]. Drawbacks include the possibility for hysteresis and dead zone effects, due to static friction [21.56].

Electrorheological (ER) and magnetorheological (MR) dampers are based on liquids whose physical behavior depends on the application of electric or magnetic fields, respectively [21.56]. These fluids follow the Bingham models: after a yielding point, they behave as viscous liquids. The property that can be changed is the yield stress itself. The MR operating principle has been used to realize VDAs in vehicles [21.57] and also in robotics [21.58]. A more accurate model and a comparison between MR and FD can be found in [21.54], where it is pointed out that MR dampers, like the FDs, present high hysteresis.

Eddy current dampers (ECDs) are magnetic devices composed of a conductive material moving through a magnetic field. Eddy currents are induced and create a damping force that is proportional to the relative velocity between the material and the magnetic field. These devices can be realized with both permanent magnets and electromagnets. In both cases, there is the possibility of designing a device whose damping can be adjusted [21.59, 60]. In one case, the damping coefficient can be controlled by varying the intensity of the magnetic field, in the other case, by modifying the geometry of the conductor, or the gap between the conductor and the magnets (the effectiveness is shown in [21.60]). Electromagnetic ECDs have the advantage of not requiring mobile parts, but have the disadvantage of consuming power for maintaining a fixed damping value. Being fluid-free and contact-free, ECD dampers are clean and wear-free. However, they typically ex-

ert low damping torque at high velocity, thus requiring gearboxes for typical robotic applications.

Fluidic dampers are probably the most widely used in robotics and general machinery and can be divided into two main categories: turbulent flow dampers (high Reynolds number) which produce a damping force proportional to the square of the relative speed; and laminar flow dampers (low Reynolds number), where the damping force is proportional to relative speed. Simple dampers are largely used in the automotive industry using an orifice through which the viscous fluid flow is turbulent. Such device generates, at a given frequency, high damping for high amplitudes, but lower damping for lower amplitudes, and thus, has the drawback of presenting long lasting residual oscillations [21.56].

21.2.13 Artificial Muscles Arrangements

The basic technologies and elements reviewed above can be arranged in many different ways to achieve actuators for soft robotics. While a detailed taxonomy of arrangements is impossible here, the main distinction is between actuators that have a constant mechanical compliance characteristic, and those which can vary stiffness. In the first class are series elastic actuators (SEA), which have been developed since the 1990s for applications in humanoid locomotion and manipulation [21.61]. An SEA may include a conventional, rigid actuator connected to a compliant element, which is in turn connected on the other end to the moving link. The compliant element can exhibit a nonlinear compliance (load-deformation) characteristic, which however, is constant in time. SEA actuators, however, may use torque and position sensing at both ends of the elastic element and modify its natural mechanical impedance by virtue of active control of the motor. The impedance range to which an SEA can be effectively controlled is centered around the natural (passive) impedance of the elastic element and is limited in span by motor torque limits and overall control bandwidth.

As opposed, VSA can vary their natural impedance directly at the physical level, so that active control can be superimposed and ultimately achieve larger ranges of effective impedance than SEA. The idea of varying the mechanical impedance of actuation comes directly from natural musculoskeletal systems, which often exhibit this feature. VSA systems can change independently the equilibrium point of the moving body part, and the stiffness of the elastic force between the equilibrium point and the displaced body position (thus effectively implementing Feldman's *equilibrium point*, or λ -model for human movement control [21.62]). Accordingly, VSAs always use two prime movers. A rough distinction can be made between VSA ar-

Fig. 21.2 Explicit stiffness variation and agonist–antagonist arrangements

Fig. 21.3a–c Three basic antagonist arrangements: (a) Simple, (b) cross-coupled and (c) bidirectional

rangements where the motors are explicitly dedicated to either equilibrium or stiffness control, and arrangements where the roles are mixed (Fig. 21.2). Explicit stiffness variation arrangements include, for example, the MIA (mechanical impedance adjuster) [21.63]), the AMASC (actuator with mechanically adjustable series compliance) [21.64], the MACCEPA (mechanically adjustable compliance and controllable equilibrium position actuator) [21.65]), and the variable stiffness joint (VS-Joint) [21.66]. Other VSA designs use instead agonist–antagonist (AA) arrangements, either in its simplest version, directly inspired to biological models, with two actuators pulling against each other [21.67, 68], or in other variants such as the cross-coupled AA [21.69] and bidirectional AA [21.70] arrangements (Fig. 21.3). It is a matter of simple calculations [21.71] to appreciate that, in an AA arrangement, the elastic elements must exhibit a nonlinear characteristic in order for the joint stiffness to be variable. If each tendon has a quadratic force–deformation relationship, then the overall joint behaves as a linear spring with variable spring constant K . A potential disadvantage of AA arrangements using unilateral (e.g., tendon) couplings between the prime movers and the driven link is that, to be able to exert a maximum torque τ at the link, two motors each capable of τ are needed. To alleviate this problem, the cross-coupled and bidirectional design introduce the possibility for an agonist actuator to also work in favour of the antagonist when required.

Recent work in soft robotics has introduced physically variable damping on the rotor dynamics in con-

junction with series elastic or VSAs [21.72]. Physically variable damping based on the ECD effect has been demonstrated in haptic interfaces [21.73]. Some authors introduced physical dampers in robotic design, both in the so-called series damping actuator configuration [21.58], or as a variable friction damper connected to an SEA [21.55], and as a variable diaphragm laminar damper module connected to a variable stiffness actuator [21.74].

21.2.14 Specifications and Performance

The increasing number of available actuators for soft robotics and the widening scope of applications are rapidly creating a need for a simple language for application developers and actuator providers to talk together. Just like the perspective user of conventional hydraulic pistons or DC motors looks at spec sheets for a concise description of the performance guaranteed by the product, a soft robot designer will need to find salient facts about different artificial muscles presented in a clear and homogeneous way. The European project VIATORS has dedicated a substantial effort to investigate what the crucial parameters of different designs are and has described a data sheet template that organizes these contents both from the designer and the user's points of view [21.75–77]. The interested reader is referred to these publications for details: it is interesting to note here that, besides the characteristics that are shared with conventional actuators (stall and peak motor torque, max velocity, power, electrical and mechanical interfaces, etc.), there are few data and curves

that are specific of soft actuators: for instance, the range of stiffness variability, and the settling time needed to

reach from minimum to maximum stiffness, or vice versa.

21.3 Modeling Actuators for Soft Robotics

To approach the analysis and control of novel actuators for soft robotics, it is necessary to describe their characteristics in terms of a mathematical model which accounts for their static and dynamic behaviors. We begin here by reviewing the familiar concept of mechanical impedance in linear time-invariant single degree of freedom (DOF) systems. Hence, in view of the fact that actuator softness control often introduces nonlinearity and time variance of the model, we proceed to generalize the concept. Finally, we move from consideration of a single actuator to modeling of multi-DOF, articulated soft robots.

21.3.1 The Mass–Spring–Damper Paradigm

The simplest example of mechanical impedance is a linear *spring*, that is, a sample of material which exhibits a proportional relation between applied force f and displacement at equilibrium y , $y = cf$. The proportionality constant c is the spring *compliance*. The inverse relation, that is, $f = ky$ introduces the spring *stiffness* $k = c^{-1}$. A spring can store an elastic energy V , whose first derivative with respect to the displacement y is the force

$$f = \frac{\partial V(y)}{y},$$

and the second derivative is the spring stiffness constant

$$k = \frac{\partial^2 V(y)}{\partial y^2}.$$

The concepts of compliance and stiffness are generalized from static (equilibrium) to dynamic cases by introducing the notion of *admittance* and *impedance*, respectively.

Consider a *damper* made of viscous material that opposes to displacements proportionally to how quick they are, that is, $f = b\dot{y}$, where b is the damping coefficient, and the inertial effects of accelerating an equivalent *mass* m of material under deformation, $f = m\ddot{y}$. In most materials, the three effects occur at the same time, and we have that the force/displacement relation is described by an ordinary differential equation. In the simple case of a single-DOF mass–spring–damper system, we have

$$f = m\ddot{y} + b\dot{y} + ky, \quad (21.1)$$

that is, a relation between two functions of time, $f(t)$ and $y(t)$. Such a differential equation describes a dynamical system. This can be regarded as a causal system if displacement (appearing with the highest-order derivative) is regarded as the effect (or output), and force as the cause (or input). Indeed, the knowledge of initial conditions on displacement, and the time course of force, determine all subsequent evolution of displacement.

Insofar as the dynamical system (21.1) is linear and time-invariant, its input–output behavior is conveniently studied via Laplace transforms from functions in the domain of time t to functions in the domain of the complex variable s . By denoting $F(s)$, $Y(s)$, $V_y(s)$ the transforms of $f(t)$, $y(t)$, and $v_y(t) = \dot{y}(t)$, respectively, one has immediately

$$\begin{aligned} F(s) &= (ms^2 + bs + k)Y(s) \\ &= (ms^2 + bs + k)s^{-1}V_y(s). \end{aligned} \quad (21.2)$$

The operator $Z(s) := (ms^2 + bs + k)s^{-1}$ is called (mechanical) *impedance* of the spring–damper–mass system. The reciprocal operator of impedance is called *admittance* $A(s)$. Notice that the admittance operator is causal, while impedance is not.

21.3.2 Nonlinear Mechanical Systems

Real materials and systems deform under applied forces in more complicated ways than (21.1): in general, the dynamics between forces and deformations include nonlinearities, and can be of an order higher than two. How do we extend to these cases the concept of *impedance* (21.2), and specifically the notions of *mass*, *stiffness* and *damping*?

There is no easy clearcut solution to this problem. A straightforward approach is to find a linear, second-order model of type (21.1), which approximates well enough the real dynamics, and take its parameters to define those of the system. In this section we briefly review some of the implications of this approach.

Consider the relation between a force $f \in F$ (F here is the set of allowed forces) applied at some point in a material sample, and the displacement $y \in Y$ measured at equilibrium at the same point and along the same direction of the force (Y the set of allowed displacements). By ideally collecting all pairs $(f(t), y(t))$ corresponding in an infinite set of experiments (indexed

by t for convenience), one can describe the relation by its graph $G \subset F \times Y$. Notice that this relation does not need to be a function: for hysteretic materials, for example, there are more admissible values of one variable corresponding to the same value of the other (Fig. 21.4).

Considering an analytic description of the graph G given by the locus $G(f, y) = 0$, at regular points of the graph a *force function* $f(y)$ is defined for values of y in a neighborhood of y_0 . The stiffness associated with such a nonlinear force function can then be defined as

$$k(y) = \frac{df(y)}{dy} = - \left(\frac{\partial G(f, y)}{\partial f} \right)^{-1} \frac{\partial G(f, y)}{\partial y}.$$

This can be generalized to a second-order, nonlinear dynamic setting by considering the relation between forces, displacements, and first- and second-order derivatives of displacements and its graph $G \subset F \times Y \times DY \times D^2Y$, comprised of 4-tuples $d(t) := (f(t), y(t), \dot{y}(t), \ddot{y}(t))$ corresponding to an idealized, infinite set of experiments. (If hysteretic nonlinearities are considered, it is necessary to describe the relation in an extended space where hysteresis state variables are introduced [21.78].) If $G(f, y, \dot{y}, \ddot{y}) = 0$ is an analytical description of the graph, and d_0 is a regular point, then a *force function* $f(y, \dot{y}, \ddot{y})$ is defined in a neighborhood of d_0 . More generally, when the system includes time-varying parameters $u(t)$ – such as, for example, a stiffening action in VSAs – one has $G(f, y, \dot{y}, \ddot{y}, u(t)) = 0$ and $f(y, \dot{y}, \ddot{y}, u)$. Following the linearization approach set out above, we can define admittance *along a given (nominal) trajectory* as the linear operator mapping small changes of the external force with respect to its nominal course, to changes in the resulting motion. To do this, consider the nonlinear ordinary differential equations (ODE) obtained by solving $G(f, y, \dot{y}, \ddot{y}, t) = 0$

Fig. 21.4 Elastic hysteresis of a rubber-like material

Fig. 21.5 A link subject to an external load and actuated by two antagonistic actuators. Nomenclature refers to actuator models used in (21.3) and (21.5), respectively

at a regular point with respect to \ddot{y} as

$$\ddot{y} = g(y, \dot{y}, f, u),$$

and its state space form, with $x \in \mathbb{R}^2$, $x_1 = y$, $x_2 = \dot{y}$, that is,

$$\frac{d}{dt} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} x_2 \\ g(x_1, x_2, f, u) \end{pmatrix}.$$

For given initial conditions $x(0) = \bar{x}_0$ and a given nominal course in time of the force $\bar{f}(t)$, let $\bar{x}(t)$ be the nominal solution obtained. The first-order approximation of the dynamics of the perturbed motion $\tilde{x}(t) = x(t) - \bar{x}(t)$ corresponding to a change in force $\tilde{f}(t) = f(t) - \bar{f}(t)$ is the linear time-varying system

$$\dot{\tilde{x}} = \begin{pmatrix} 0 & 1 \\ -\kappa(t) & -\beta(t) \end{pmatrix} \tilde{x} + \begin{pmatrix} 0 \\ \mu(t) \end{pmatrix} \tilde{f}.$$

For the given system and the given motion, hence, we can define instantaneous mass, stiffness, and damping coefficients as

$$\begin{aligned} m(t) &= \mu^{-1}(t); \\ b(t) &= m(t)\beta(t); \\ k(t) &= m(t)\kappa(t). \end{aligned}$$

Example 21.1

Consider the link in Fig. 21.5, actuated by two antagonistic actuators (with a role vaguely similar to that of the biceps and triceps muscles at the elbow), with a quadratic damping and subject to gravity and to an external torque load τ_e . The system dynamics are

$$I\ddot{\theta} + \beta\dot{\theta}|\dot{\theta}| - \tau_b + \tau_t - mgl \sin \theta - \tau_e = 0.$$

Fig.21.6a,b Generalized stiffness (a) (dashed is without gravity term) and generalized damping for the example with actuators as in (21.3), subject to a unit step in external torque at $t = 1$ s, and (b) with time-varying activation $u_b(t) = u_t(t)$ linearly increasing from 0 at $t = 1$ s to 1 at $t = 15$ s. Numerical values used in simulation: $I = 0.05 \text{ Nm s}^2$, $mgl = 0.1 \text{ Nm}$, $\beta = 1 \text{ Nm s}^2$, $\alpha = 1 \text{ Nm}$, $\tau_{\max} = 2 \text{ Nm}$

Fig.21.7a,b Generalized stiffness (a) (dashed is without gravity term) and generalized damping for the example with actuators as in (21.5), subject to a unit step in external torque at $t = 1$ s, and (b) with time-varying reference angle $u_b(t) = u_t(t)$ linearly decreasing from $\pi/3$ at $t = 1$ s to 0 at $t = 15$ s. Numerical values used in simulation as in Fig. 21.6, except for $\alpha = 0.3 \text{ Nm}$

Assume first that the two actuators generate torques according to the model [21.67]

$$\begin{aligned}\tau_b &= (\tau_{\max} - \alpha\theta_b) u_b, \\ \tau_t &= (\tau_{\max} - \alpha\theta_t) u_t,\end{aligned}\tag{21.3}$$

where $\theta_b = (\pi/2 + \theta)$, $\theta_t = (\pi/2 - \theta)$, τ_{\max} is the maximum isometric torque, u_b , u_t are the normalized con-

traction parameters ($0 \leq u \leq 1$, $u = u_b, u_t$), and α is a constant assumed to be equal for the two actuators. We easily obtain $m = I$ for the generalized mass, $b(\dot{\theta}) = 2\beta|\dot{\theta}|$ for the generalized damping, and

$$k(\theta, u) = \alpha(u_b + u_t) - mgl \cos(\theta)\tag{21.4}$$

for the generalized stiffness. In the latter expression, the

role of a gravity-induced term and that of a co-activation stiffness term are apparent.

If a different actuator model is adopted, namely [21.79]

$$\begin{aligned}\tau_b &= -\alpha(\theta_b - u_b)^2, \\ \tau_t &= -\alpha(\theta_t - u_t)^2,\end{aligned}\quad (21.5)$$

where u_b , u_t are now interpreted as the rest lengths of the actuators, one has

$$k(\theta) = 2\alpha(\pi - \lambda_b - \lambda_t) - mgl \cos(\theta).$$

The values of stiffness and damping for the two examples above, corresponding to time-varying values of the control parameters, are reported in Figs. 21.6 and 21.7, respectively. ■

So far, we have considered only impedance for second-order dynamical systems – basically modeling actuators with a single moving element that dominates the system inertia. In practice, one may encounter higher order systems because of either (i) more complex

actuator systems, or (ii) the connection of actuators and links in an articulated robot structure. The latter case will be discussed in Sect. 21.4.

Examples of actuators with higher order dynamics are the arrangements in Fig. 21.3: if the agonist and antagonist prime movers as well as the driven link have nonnegligible inertia, the dynamics are at least of sixth order. If the system is linear, admittance can still be defined as the sixth-order transfer function from link torque to link displacement: however, there is no natural way of associating an equivalent single mass, spring or damper coefficient. To recover these notions, an approach could be to apply some form of model reduction of the higher order dynamics to second order [21.80]. However, model reduction is all but an obvious procedure, as the approximate heavily depends on how the similarity of response between dynamics is measured. With nonlinear systems, the problem is clearly even more complicated. Overall, the topic is definitely worth further investigation, which should take into account what are the ultimate practical goals of defining impedance parameters.

21.4 Modeling Soft Robots

In this section, a brief introduction of dynamic models for soft robots is given, starting with a quite general lumped-parameter formulation and successively introducing several simplifying assumptions.

A soft robot with lumped elasticities can be imagined as a set of directly actuated rigid bodies with configuration $\theta \in \mathbb{R}^m$, connected to the indirectly actuated rigid bodies (with configuration vector $q \in \mathbb{R}^n$) through viscoelastic forces, as exemplarily sketched in Fig. 21.8. The entire configuration space of the system is denoted by $x = (\theta, q)$, $x \in \mathbb{R}^{(n+m)}$. A quite general abstraction of a compliant robot, which can be used for the generic design of controllers, is given by

$$\mathbf{M}(x)\ddot{x} + \mathbf{c}(x, \dot{x}) + \left(\frac{\partial V(x)}{\partial x}\right)^T + d(x, \dot{x}) = \begin{pmatrix} \tau_m \\ \tau_{\text{ext}} \end{pmatrix}, \quad (21.6)$$

with $\mathbf{M}(x)$ being the inertia matrix, $\mathbf{c}(x, \dot{x})$ the Coriolis and centrifugal vector, V the potential energy of the elastic element and of the gravity forces, $\tau_m \in \mathbb{R}^m$ the actuator generalized forces acting as control inputs, and $\tau_{\text{ext}} \in \mathbb{R}^n$ the external torques acting on the robot as a disturbance. The most relevant property of this struc-

ture is its underactuation, meaning that the system has less control inputs (m) than its configuration space dimension ($n + m$). However, in contrast to other purely inertially coupled underactuated systems (for example multiple pendulums such as the Acrobot [21.81].), for the considered robots $V(x)$ is [21.82] positive definite, implying that a unique equilibrium point exists for each external torque with actuators in a fixed configu-

Fig. 21.8 A soft robot can be imagined as a set of directly actuated rigid bodies with configuration θ , connected to the indirectly actuated rigid bodies (with configuration coordinates q through elastic forces). Note that in general, inertial couplings, not depicted in the figure, might exist as well

Fig. 21.9 Typical shapes of elastic torque characteristics, denoted by nonlinear deflection dependency and a family of linear curves, parameterized by σ

ration $\theta = \theta_0$ and that the linearization of the system around an equilibrium point $\{\mathbf{x} = \mathbf{x}_0, \dot{\mathbf{x}} = 0\}$ is controllable. Typically, $V(\mathbf{x}) = V_G(\mathbf{x}) + V_\tau(\mathbf{x})$, that is, the potential function is the sum of a gravity potential V_G and an elastic potential V_τ . The elastic potential function $V_\tau(\mathbf{x})$ is a convex function (Fig. 21.9), increasing strongly enough to compensate for the destabilizing effects of V_G , such that $V(\mathbf{x})$ is convex as well. Furthermore, the system contains in general a dissipative friction force $\mathbf{d}(\dot{\mathbf{x}}, \mathbf{x})$ with $\dot{\mathbf{x}}^T \mathbf{d}(\dot{\mathbf{x}}, \mathbf{x}) \leq 0$. Note that between the directly and indirectly actuated states, there can exist also inertial couplings, as depicted in Fig. 21.10. Therefore, $\mathbf{M}(\mathbf{x})$ is in general a fully coupled matrix.

While at first sight looking pretty general and simple, model (21.6) is actually quite complex due to the full, parallel inertia and stiffness coupling. This can be seen by rewriting it in the less compact form

$$\begin{pmatrix} \mathbf{M}(\mathbf{q}, \theta) & \mathbf{Q}(\mathbf{q}, \theta) \\ \mathbf{Q}^T(\mathbf{q}, \theta) & \mathbf{B}(\mathbf{q}, \theta) \end{pmatrix} \begin{pmatrix} \ddot{\mathbf{q}} \\ \ddot{\theta} \end{pmatrix} + \mathbf{c}(\mathbf{q}, \theta, \dot{\mathbf{q}}, \dot{\theta}) + \mathbf{g}(\mathbf{q}, \theta) + \begin{pmatrix} \frac{\partial V(\mathbf{q}, \theta)^T}{\partial \mathbf{q}} \\ \frac{\partial V(\mathbf{q}, \theta)^T}{\partial \theta} \end{pmatrix} + \mathbf{d}(\dot{\mathbf{q}}, \dot{\theta}) = \begin{pmatrix} \boldsymbol{\tau}_{\text{ext}} \\ \boldsymbol{\tau}_m \end{pmatrix}. \quad (21.7)$$

The above formulation emphasized the inertial coupling terms $\mathbf{Q}(\mathbf{q}, \theta)$ as well as possible dependencies of the inertial properties on both motor and link configuration.

Although (21.6) is the only formulation general enough to describe most soft robot designs with lumped elasticities encountered in the literature so far, it might pose substantial difficulties in controller design, that is, for the fact that it is not necessarily feedback-linearizable. (See, for example, the full dynamic model

Fig. 21.10 In this example, the directly and the indirectly actuated states are both inertially and elastically coupled. This leads to a fully coupled inertia matrix in the dynamics equations

of flexible joint robots from [21.83, 84], which is not static state-linearizable.) Therefore, several simplifying assumptions are encountered in the literature, justified by particular robot design choices:

- A1: The system has no inertia coupling between the directly and the indirectly actuated states, but only elastic couplings. This assumption includes the usual neglecting of motor gyroscopic effects for high-gear actuators [21.85] as well the neglect of small inertial couplings usually appearing in the VIA mechanisms [21.86] and imposes some restrictions related to mechanical design (Fig. 21.10 for a counter-example). The assumption leads to a block-diagonal structure of the mass matrix.
- A2: The gravity potential energy as well as the variation of the mass matrix is only due to the link-side variables \mathbf{q} . This implies that also the Coriolis and centrifugal torques are only depending on \mathbf{q} and $\dot{\mathbf{q}}$.
- A3: The dynamics of the stiffness adjusting mechanism is negligible; the system dynamics is mainly described by the states \mathbf{q} and a directly actuated state vector $\boldsymbol{\theta} \in \mathbb{R}^n$ of the same dimension as \mathbf{q} , corresponding to one principal motor per joint. The remaining $m - n$ motor coordinates of the stiffness adjusters are treated as parameters and are usually denoted by $\boldsymbol{\sigma}$. In this case, the elastic potential reduces to $V_\tau(\mathbf{q} - \boldsymbol{\theta}, \boldsymbol{\sigma})$. This is already a quite restricting assumption, applying mainly for SEA-type actuators with a dedicated stiffness adjuster, as typically used in the design of large joints of arms and legs. The model is practically valid only if stiffness is changed off-line or at low rate. Classical antagonistic actuators including two equally sized motors, as used, for example, in some robotic hand designs [21.87] do not fulfill this assumption.
- A4: A further particular choice of $V_\tau(\mathbf{q} - \boldsymbol{\theta}, \boldsymbol{\sigma})$ is that of a quadratic function in $\mathbf{q} - \boldsymbol{\theta}$ such that the

joint torque is

$$\tau = \frac{\partial V(\phi, \sigma)^T}{\partial \phi} = \mathbf{K}(\sigma)\phi, \quad (21.8)$$

with $\phi = q - \theta$. This implies that the stiffness of the actuator depends only on the stiffness adjuster and not on the deflection of the springs [21.82]. This assumption introduces additional simplifications in controller design, applies however only to a restricted subclass of soft actuators.

The model, under assumptions A1, A2 reduces to

$$\begin{pmatrix} \mathbf{M}(q) & \mathbf{0} \\ \mathbf{0} & \mathbf{B} \end{pmatrix} \begin{pmatrix} \ddot{q} \\ \ddot{\theta} \end{pmatrix} + \begin{pmatrix} c(q, \dot{q}) \\ \mathbf{0} \end{pmatrix} + \begin{pmatrix} g(q) \\ \mathbf{0} \end{pmatrix} + \left(\frac{\partial V(q, \theta)^T}{\partial q} \right) + d(\dot{x}) = \begin{pmatrix} \tau_{\text{ext}} \\ \tau_m \end{pmatrix}. \quad (21.9)$$

Note that the model above does not make any further specification regarding the dimensions m and n , thus covering a broad range of robots, including as particular cases:

- The classical, fully antagonistic case with $m = 2n$.
- The quite popular $n + 1$ tendon design for robot fingers which leads to $m = n + 1$. More generally, $2n > m > n$ tendon designs are encountered.
- Synergy hands with $m < n$, where each synergistic actuator acts over springs on several links.
- Multi-articular muscles, as mostly existing in biological systems.

Under assumption A3 the size of θ reduces to the size of q ($m = n$) and the model becomes

$$\begin{pmatrix} \mathbf{M}(q) & \mathbf{0} \\ \mathbf{0} & \mathbf{B} \end{pmatrix} \begin{pmatrix} \ddot{q} \\ \ddot{\theta} \end{pmatrix} + \begin{pmatrix} c(q, \dot{q}) \\ \mathbf{0} \end{pmatrix} + \begin{pmatrix} g(q) \\ \mathbf{0} \end{pmatrix} + \begin{pmatrix} \tau \\ -\tau \end{pmatrix} + d(\dot{x}) = \begin{pmatrix} \tau_{\text{ext}} \\ \tau_m \end{pmatrix}, \quad (21.10)$$

with $\tau^T = \partial V(\phi, \sigma) / \partial \phi$. It is then quite close to the flexible joint models treated in detail in Chap. 11. The similarity becomes even stronger, when the torque is described by (21.8) under assumption A4. Note that the dimension of θ in (21.10) is half of the dimension of the same variable in (21.9) since the dynamics of the stiffness adjuster is neglected.

21.5 Stiffness Estimation

Strictly speaking, impedance is a differential operator relating physical quantities (forces and displacements). Rather than a direct measurement, the process of characterizing impedance of a system is therefore a process of *dynamical system identification*.

In typical procedures for impedance measurement of material samples, such as, for example, organic tissue samples, the measured system is put into mechanical contact with another mechanical system, the instrument. The resulting compound dynamical system is then subject to a dynamical excitation of different nature, and data are collected. Experiments are typically conducted by touching the sample with a small, hard, vibrating probe. On the basis of measurements on the probe motion (displacement y , velocity \dot{y} or acceleration \ddot{y}) and the applied force f , the mechanical impedance of the sample is inferred. A vast literature is available on the metrology of impedance of materials, and the reader is referred there for a detailed survey [21.88].

The problem of measuring impedance in articulated systems is obviously more complex than for material samples, but is of great relevance to several fields –

including notably human movement science and neuroscience, who strive to understand how humans vary and control impedance in their movements. When the hand is slightly perturbed during arm movements, it tends to return to the undisturbed trajectory [21.20, 89], as if the hand would be connected to a spring along the planned trajectory. This spring-like property stems mainly from muscle elasticity and the stretch reflex, which produce – through the complex leverage of muscles at different limb configurations – a restoring force toward the undisturbed trajectory. Methods to characterize the mechanical impedance of human limbs have been the subject of extensive research [21.90–98]. Current protocols for identifying impedance in human motion typically recur to experiments in which perturbations are purposefully injected in the system, and their effects are measured. In artificial robotic systems, impedance parameters can also be calculated on the basis of a precise description of the model (wherever this is available), or obtained through accurate calibration procedures. In both natural and artificial systems, it would be of great utility to have a method which could identify impedance in real time, without per-

turbing the normal execution of the task, and robustly to inaccurate modeling and to time-varying parameters altering calibration results. Of particular interest in robotics is the application of such methods to VIAs for soft robotics. As discussed, these can be implemented in a variety of ways and arrangements, but all designs share a fundamentally unavoidable nonlinear behavior, which makes stiffness measurement a tough problem.

According to the description of impedance as a differential operator, its characterization can be cast as an identification problem of a dynamical system. To date, the literature on this subject is not abundant, and it can be subdivided in two main approaches, that is, parametric and nonparametric identification. Parametric approaches postulate that a model of the actuator generating variable stiffness is known in its structure, but that some of its parameters are unknown. Nonparametric approaches do not use such an assumption, and are thus more general; however, as we will see, nonmodel-based observers have the disadvantage that they cannot *go to sleep* after reaching convergence, and require persistent excitation to stay tuned to variable impedance.

21.5.1 Observers for Linear Impedance

To introduce the problem, let us first consider the case of constant linear impedance identification in the elementary system (21.1)

$$f = m\ddot{y} + b\dot{y} + ky,$$

where we assume that m , b , k are unknown but constant, while y and f are available from position and force measurements at one of the ends of the compliant elements.

Before embarking in building an algorithm to estimate impedance, it is important to establish that the problem is well posed, that is, that a solution exists and is unique. To this purpose, consider an extended state vector

$$z = \left(y \quad \dot{y} \quad -\frac{k}{m} \quad -\frac{b}{m} \quad \frac{1}{m} \right),$$

and rewrite the dynamics (21.1) as a nonlinear dynamical system

$$\dot{z} = \begin{pmatrix} z_2 \\ z_1 z_3 + z_2 z_4 \\ 0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 0 \\ z_5 \\ 0 \\ 0 \\ 0 \end{pmatrix} f, \quad (21.11)$$

$$y = h(z) = z_1.$$

The identification of the impedance parameters can thus be cast as a nonlinear observability problem, that is, from the knowledge of the input f and output y , estimate the initial state $z(0)$, and in particular its three last components which completely determine the linear impedance. The observability codistribution for this system is

$$\Omega(z) = \text{span} \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ z_3 & z_4 & z_1 & z_2 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ z_3 z_4 & z_3 + z_4^2 & z_2 + z_1 z_4 & z_1 z_3 + 2z_2 z_4 & 0 \\ 0 & 0 & 0 & z_5 & z_4 \end{pmatrix}.$$

It is easy to check that, for m , b , $k > 0$, the observability codistribution has codimension zero for all states, except if $z_1 = z_2 = 0$. Hence, whenever the system is not in stationary equilibrium, the three linear constant impedance parameters can, in principle, be reconstructed from position and force measurements.

To actually estimate the impedance in this case, different methods can be adopted. These include standard off-line identification techniques (which exploit the linear nature of the regressor for the unknown parameters), such as, for example, in [21.99], or on-line nonlinear state observers (e.g., extended Kalman filters) applied to system (21.11) [21.100].

21.5.2 Variable Stiffness Observers

Unfortunately, the generalization of the above straightforward approach to the case when impedance is nonlinear and/or time-varying is not trivial. To convince oneself, it is sufficient to consider the case that, instead of the linear spring term ky , a nonlinear and time-varying spring function $s(y, u(t))$ is introduced in (21.1), that is

$$f = m\ddot{y} + b\dot{y} + s(y, u). \quad (21.12)$$

In the $s(y, u(t))$ term, u indicates an exogenous input that commands changes in stiffness. For instance, disregarding gravity in Example 21.1 earlier, u would represent the co-activation term $u_b + u_t$ in (21.4).

21.5.3 Parametric Estimation

A first approach to identify stiffness can be based on the assumption that the arrangement of the variable stiffness actuator is known (Fig. 21.2), and that a parametric

description of the spring function is available, for example, in terms of a finite basis expansion. In this case, parametric stiffness observers have been proposed that work *on the motor side*, that is, considering the dynamics of each motor as

$$\tau = J\ddot{\theta} + b\dot{\theta} - f(\phi), \quad (21.13)$$

where τ is the torque of the motor, J and b are the motor inertia and damping, respectively, and $\phi = \theta - q$ is the displacement angle with q being the link angle. These parameters and signals being known or measured, the problem is to estimate the stiffness $\sigma(\phi) = \frac{\partial f}{\partial \phi}$, assuming it can be approximated by the truncated Taylor expansion

$$\sigma_i(\phi_i) \approx \sum_{j=0}^N \alpha_j^i \frac{(\phi_i)^j}{j!}.$$

In [21.101], a parametric stiffness observer is presented to solve this problem. The idea is to first obtain an estimation of the spring force function $f(\phi)$ by combining a modified kinematic Kalman filter for the estimation of the first derivative of q and a first-order filter. Then $f(\phi)$ is approximated by a power series whose coefficients are estimated by a least-squares algorithm. Finally, σ is obtained by analytically differentiating the Taylor expansion. The method has been demonstrated to work well in simulation, and encouraging experimental results have been reported. The method is somewhat sensitive to the choice of several parameters, which require careful tuning. Subsequently, [21.102, 103] proposed algorithms based on differential algebra and modulating functions, respectively, that improved convergence and robustness avoiding taking any derivatives and are very easy to tune.

21.5.4 Nonparametric Estimation

When no information on the structure of f or on the variable $u(t)$ is available, the only possible approach

is *on the link side*, that is trying to estimate the joint stiffness looking only at the link dynamics, without assuming any structure for the spring stiffness function. A nonparametric method was proposed in [21.104] to measure stiffness in a system such as (21.12), which can be easily derived from the idea of differentiating (21.12) once with respect to time

$$\dot{f} = m\ddot{y} + b\dot{y} + \sigma\dot{y} + s_u\dot{u},$$

where

$$s_u := \frac{\partial s(y, u)}{\partial u}.$$

The method is based on the continuous update of an estimate $\hat{\sigma}$ of stiffness. Based on a best effort prediction for the link torque \hat{f} as

$$\hat{f} = m\ddot{y} + b\dot{y} + \hat{\sigma}\dot{y},$$

it was shown that, under mild assumptions, the update law

$$\dot{\hat{\sigma}} = \alpha(\dot{f} - \hat{f})\text{sgn}(\dot{y}), \quad (21.14)$$

with $\alpha > 0$ makes $\hat{\sigma}(t)$ converge to the true stiffness value $\sigma(t)$ within a uniformly ultimately bounded error. The error bound is affected by errors in obtaining filtered approximations of derivatives of the position $y(t)$ and of the applied force $f(t)$, and in estimating mass and damping coefficients m and b , respectively. Conversely, the error can be reduced by increasing the gain factor α . As opposed to parametric methods, no assumptions are made on the function $s(y, u)$, except that it is smooth and bounded in both arguments. The method has been experimentally demonstrated to work well, practically converging to the true stiffness value in all circumstances except when stiffness is varied without moving the link. In this case (where it is indeed theoretically impossible to observe stiffness *from the link side*), the method of [21.104] simply stops updating the stiffness estimate, to resume as soon as a sufficiently rich dynamic excitation is again applied to the link.

21.6 Cartesian Stiffness Control

21.6.1 Cartesian Impedance Control

The Cartesian impedance control paradigm is one of the most widely used manipulation control approaches in modern robotics to handle contact situations [21.90, 105, 106]. It combines the advantages of compliant manipulation with the ease and intuitiveness of a task description in Cartesian coordinates. Indeed, this con-

trol technique has been one of the motivations for the research of variable-impedance-actuated robots. Therefore, it is a natural aim to analyze and transfer Cartesian impedance control concepts to soft robots.

The goal addressed in this section is to realize a desired Cartesian impedance behavior at the tool center point (TCP) of a variable-impedance-actuated robot. Following a central paradigm of VIA, the mechanical

robot parameters need to be tuned such that the desired behavior is naturally achieved on a mechanism level to the largest extent possible.

With the model from (21.10), the **VIA** joints shall be adjusted to realize a Cartesian stiffness. The stiffness behavior is described by a constant stiffness matrix $\mathbf{K}_C = \partial \mathbf{f} / \partial \mathbf{x} \in \mathbb{R}^{m \times m}$ as the relation between the Cartesian wrench \mathbf{f} and the Cartesian displacement \mathbf{x} . The n passive and adjustable joint stiffness components provide the diagonal matrix $\mathbf{K}_J = \partial \boldsymbol{\tau} / \partial \mathbf{q} \in \mathbb{R}^{n \times n}$ with the joint torques $\boldsymbol{\tau}$ and the joint positions \mathbf{q} . Decoupled joint compliance is assumed. The mapping from the Cartesian stiffness space to the joint stiffness space is given by \mathcal{T} : $\mathbf{K}_J = \mathcal{T}(\mathbf{K}_C)$. This transformation can be written as

$$\begin{aligned} \mathbf{K}_J &= \frac{\partial \boldsymbol{\tau}}{\partial \mathbf{q}} = \frac{\partial (\mathbf{J}(\mathbf{q})^T \mathbf{K}_C \Delta \mathbf{x})}{\partial \mathbf{q}} \\ &= \mathbf{J}(\mathbf{q})^T \mathbf{K}_C \mathbf{J}(\mathbf{q}) - \frac{\partial \mathbf{J}(\mathbf{q})^T \mathbf{K}_C \Delta \mathbf{x}}{\partial \mathbf{q}}; \end{aligned} \quad (21.15)$$

$\mathbf{J}(\mathbf{q}) = \frac{\partial \mathbf{f}(\mathbf{q})}{\partial \mathbf{q}}$ is the manipulator Jacobian, where $\mathbf{f}(\mathbf{q})$ is the forward kinematics mapping. $\Delta \mathbf{x} = \mathbf{x}_d - \mathbf{x}$ is the Cartesian position error between the desired and the actual position. The first part of (21.15) reflects the stiffness around the equilibrium point. The second part of (21.15) is due to the change of the Jacobian [21.107].

The Cartesian stiffness at the equilibrium position ($\Delta \mathbf{x} = 0$), resulting from a specific joint stiffness, can be obtained by solving the inverse problem of (21.15), $\mathbf{K}_C = \mathcal{T}^{-1}(\mathbf{K}_J)$. Note that at the equilibrium position the second term in (21.15) vanishes. Using compliance matrices $\mathbf{C}_\bullet = \mathbf{K}_\bullet^{-1}$, it results from

$$\mathbf{C}_C = \mathbf{J}(\mathbf{q}) \mathbf{C}_J \mathbf{J}(\mathbf{q})^T \quad (21.16)$$

that

$$\mathbf{K}_C = (\mathbf{J}(\mathbf{q}) \mathbf{K}_J^{-1} \mathbf{J}(\mathbf{q})^T)^{-1}. \quad (21.17)$$

In [21.108], it was investigated that an arbitrary Cartesian stiffness matrix with three translational and three rotational stiffnesses ($\mathbf{K}_C \in \mathbb{R}^{6 \times 6}$) can hardly be reached by a 7-DOF robot, even exploiting the null space. Bounds are imposed by the technical realization, namely the diagonal joint stiffness matrix or mechanical **VSA** stiffness limits. Furthermore, the transformation of the joint stiffness into the Cartesian space is strongly determined by the robot kinematics and pose.

To overcome these restrictions and improve the stiffness tracking performance, one can use the passive stiffness in combination with an active impedance controller [21.109], which widely extends the achievable Cartesian stiffness range. Active control adapts

the stiffness in a wider range, and the elastic elements are capable of absorbing impacts and increase the energy efficiency. By combining the two concepts, one can benefit from the individual advantages. The serial interconnection of the active stiffness $\mathbf{K}_{\text{active}}$ and the passive one $\mathbf{K}_{\text{passive}}$ results in an overall stiffness \mathbf{K}_{res} (Fig. 21.11)

$$\mathbf{K}_{\text{res}}^{-1} = \mathbf{K}_{\text{active}}^{-1} + \mathbf{K}_{\text{passive}}^{-1}. \quad (21.18)$$

To compute the active and passive stiffness components, a two-step optimization algorithm can be used [21.109]. It achieves first a passive stiffness as close as possible to the desired one and secondly designs the active stiffness to minimize the residual.

21.6.2 Independent Position and Stiffness Control

Variable stiffness robots are well suited for manipulation tasks involving the interaction with an environment. Such tasks are often specified by a robot pose trajectory and an associated stiffness trajectory. As **VSA** robots allow us to vary joint position and stiffness in a mechanical way, a direct approach is to adjust the respective position or stiffness inputs. Depending upon the joint setup, these inputs are reflected by distinct actuators [21.66] or can be achieved by a simple coordinating transformation arising from the coupling of actuators [21.69]. The underlying idea is to embed and thereby achieve the desired robot behavior on a mechanical level. Additional control goals, especially important in the presence of disturbances, are the minimization of deflections and the suppression of vibrations.

The solutions to achieve independent control of link motion and stiffness can be classified in two categories:

- One class of controllers exploits the knowledge of system models.

In [21.110] and [21.111], feedback linearization approaches are used to transform the robot dynamics

Fig. 21.11 Combination of active impedance controller (brown springs) with passive compliance (black springs) to achieve a desired Cartesian stiffness

into an equivalent model of simpler form. A decoupled chain of integrators can be achieved, as long as system inversion is possible. The simple structure of the equivalent dynamics allows for simultaneous decoupling and accurate tracking of motion and stiffness reference profiles. However, the abstraction of the robot dynamics hinders the implementation of performance criteria.

Another model-based approach aims to achieve a reduced order model [21.112]. Therefore, separate dynamics are identified in the robot system, namely the arm, the positioning actuators, and the stiffness actuators. The independence of these dynamics is shown by a singular perturbation analysis. A cascaded control structure is based upon this analysis. The abstraction that this class of controllers provides, allows for theoretical simplicity and design flexibility. On the other hand, robot performance and robustness in the presence of model uncertainty are not guaranteed. High-model accuracy and high derivatives of states are often required. Furthermore, to conform with the idea of embodiment additional effort is necessary, as the controllers often introduce a different robot behavior.

- The second class of controllers are energy-shaping-based controllers.

One of the first controllers in this category was presented in [21.7]. The controller acts on motor position and uses a transformation to independently control the joint position and stiffness. The controller is validated on a one-DOF VSA joint.

An extension and a generalization have been presented in [21.113]. The control design formulation is valid for a quite general form of underactuated Euler–Lagrange systems including variable impedance robots. Herein, the controller action can be interpreted as shaping of the potential and kinetic robot energy ensuring system passivity.

A general task is described as to control k independent output variables given by $\mathbf{q} = \mathbf{h}(\mathbf{x})$ to desired constant values $\mathbf{q}_d \in \mathbb{R}^k$. $\mathbf{x} \in \mathbb{R}^n$ is the vector of generalized coordinates, where $n = 2k$ is the usual case for VSA robots. Given the structure of VSA robots (21.10), a new variable $\bar{\mathbf{q}}$ can be found. This is a collocated (directly actuated) variable, which is statically equivalent to the noncollocated (indirectly actuated) \mathbf{q} . Using this collocated variable for a passive feedback ensures stability and can be interpreted as shaping the potential energy of the system.

The variable $\bar{\mathbf{q}}$ is achieved by solving the static solution of the link side equation

$$\boldsymbol{\tau} + \mathbf{g}(\mathbf{q}) = \mathbf{0} \quad (21.19)$$

for \mathbf{q} . Except for very simple cases, this equation has to be solved numerically. Due to the convex nature, this is a fast and numerically robust task in practice. Consequently, the controller

$$\mathbf{u} = \mathbf{g}(\bar{\mathbf{q}}) - \mathbf{J}_{\bar{\mathbf{q}}}^T(\boldsymbol{\theta}) \mathbf{K}_p(\bar{\mathbf{q}} - \mathbf{q}_d) - \mathbf{K}_d \dot{\boldsymbol{\theta}} \quad (21.20)$$

stabilizes the desired position \mathbf{q}_d ; $\mathbf{g}(\bar{\mathbf{q}})$ is a feed forward term, compensating for the gravity. The use of $\bar{\mathbf{q}}$ enables arbitrarily low controller gains even for large displacements from the equilibrium. $\mathbf{J}_{\bar{\mathbf{q}}}$ is a Jacobian mapping the collocated variable on the statical equivalent $\bar{\mathbf{q}}$. Global asymptotic stability based on LaSalle's invariance theorem can be shown.

The approach can be extended in order to include also the feedback of torque and torque derivative, with the effect of reducing the apparent actuator inertia and friction. This allows improving the transient performance while remaining within the passivity framework. A torque feedback of the form

$$\boldsymbol{\tau}_m = \mathbf{B}\mathbf{B}_{\theta}^{-1}\mathbf{u} + (\mathbf{I} - \mathbf{B}\mathbf{B}_{\theta}^{-1})\boldsymbol{\tau}, \quad (21.21)$$

with a new control input \mathbf{u} leads to a new subsystem with scaled motor inertia

$$\mathbf{B}_{\theta}\ddot{\boldsymbol{\theta}} + \boldsymbol{\tau} = \mathbf{u}. \quad (21.22)$$

The torque controller can therefore be interpreted as a scaling of the kinetic energy of the rotors in order to reduce the vibrations caused by the joint flexibility. The controlled system allows again a passive representation.

The energy shaping approach provides excellent performance in the static case and for well damped systems. Some joints show low intrinsic damping to enable joint torque estimation and energy efficiency. In this case it is desirable to add additional damping via control or to include a physical variable damping element. Several damping control structures can be considered. A simple gain scheduling approach for a one-DOF system has been presented in [21.114]. Local linear sub problems are identified on which a linear quadratic regulator (LQR) state feedback controller is designed. The nonlinearity of the robot dynamics requires to adapt the controller poles dependent on the system state, which is especially hard for the multi-joint robots.

A physically motivated state feedback control approach for multi-DOF VSA robots has been presented in [21.115] using an eigenvalue-based modal decomposition.

21.7 Periodic Motion Control

Robotic tasks, such as walking, jumping, running, and some pick-and-place motions, are essentially periodic motions. During these tasks, the natural oscillatory dynamics of compliant actuators can be ideally exploited to increase performance and energy efficiency. It is well known that fast running animals store and recover a substantial amount of energy during a running gait period in their tendons and muscles. Also human running strongly relies on elastic energy storage.

Exciting periodic motions in a highly nonlinear multibody system by using nonlinear elastic actuators is, however, a nontrivial task. While modal oscillations and their control are very well understood for linear systems, the nonlinear generalization is a very active topic of research. Since we consider that the ability to perform (quasi) periodic motions with high velocity and force at low weight will be one of the major benefits of soft robots, we dedicate an extensive section to this topic.

The topic of exploiting intrinsic elasticity for periodic motions was addressed in robotics by [21.116–120] among others. Two basic approaches can be distinguished:

- Tracking an *arbitrary* desired periodic trajectory, or enforcing an arbitrary oscillatory closed-loop behavior, by control while simultaneously adjusting the compliance of the actuator such that the control effort is minimal.
- Exciting and sustaining *intrinsic* oscillatory dynamics of the compliantly actuated robotic system by control. Completion of a given task implies that this intrinsic oscillation modes correspond to the task by the initial mechanical design and by online adjustment of the robot configuration and of its intrinsic actuator stiffness.

Depending on the design of the compliantly actuated robotic system, the above control approaches have to cope with underactuation, model nonlinearities, and multiple-DOF structures.

21.7.1 Periodic Motion Tracking and Stiffness Adaptation

The idea of tracking a periodic trajectory in the link-side variables q with minimal torque is inspired by classical rigid-robot control. The approach [21.117] considers, for example, robotic systems with elastic elements *in parallel to the main actuators*

$$\mathbf{M}(q)\ddot{q} + (\mathbf{C}(q, \dot{q}) + \mathbf{D})\dot{q} + g(q) + \mathbf{K}(q - \theta) = \tau. \quad (21.23)$$

Since θ is assumed to be constant here, the model reduces in this case to a fully actuated robot dynamics with parallel elasticity, being thus simpler than (21.6).

The objectives of the controller are:

1. Tracking a periodic trajectory $q_d(t+T) = q_d(t)$ with period T such that $q(t) \rightarrow q_d(t)$
2. Minimizing the actuator torque τ by optimizing the stiffness \mathbf{K} .

Considering the actuator torque required to generate the desired motion

$$\tau_d = \mathbf{M}(q_d)\ddot{q}_d + [\mathbf{C}(q_d, \dot{q}_d) + \mathbf{D}]\dot{q}_d + g(q_d) + \mathbf{K}(q_d - \theta),$$

a stiffness matrix \mathbf{K}_{opt} is defined to be optimal if it minimizes the cost function

$$\mathbf{J}(\mathbf{K}) = \int_{iT}^{iT+T} \tau_d(\mathbf{K}, t)^T \tau_d(\mathbf{K}, t) dt. \quad (21.24)$$

In the case of the single-DOF system

$$m\ddot{q} + d\dot{q} + kq = \tau, \quad (21.25)$$

with constant system parameters $m, d, k > 0$, the desired, sinusoidal motion $q_d(t) = a \sin \omega t$ obviously minimizes the cost function (21.24), when the stiffness is $k_{\text{opt}} = m\omega^2$. With the optimal stiffness, the sinusoidal motion with an arbitrary amplitude $a > 0$ corresponds to a resonance motion, since the angular frequency $\omega = \sqrt{k_{\text{opt}}/m}$ of the desired trajectory corresponds to the resonance frequency of the system (21.25).

The method proposed in [21.117] extends this simple concept of resonance to the multi-DOF system (21.23). Various online or offline optimization algorithms can be defined to minimize the cost function (21.24). For example, [21.117] uses the parameter adjustment law

$$\dot{k} = \Gamma \text{diag}(q - \theta) \left[\dot{\tilde{q}} + \mathbf{K}_B s(\tilde{q}) \right]$$

to adapt the stiffness $\mathbf{K} = \text{diag}(k)$. The controller gain matrix \mathbf{K}_B is positive definite and diagonal and the adaptation gain Γ is a positive definite matrix. The rationale behind this law is to increase the stiffness whenever the elastic deflection $(\theta - q)$ has the opposite sign to the tracking error. In this case, a stiffness increase reduces the tracking error. The stiffness is reduced whenever the elastic torque increases the tracking

error. In particular, the control error $\tilde{q} = q - q_d$ is saturated by functions $s_i(\tilde{q}_i)$ satisfying certain boundedness constraints. These saturated functions are important for the stability analysis in [21.117].

The paper [21.121] considers dynamic systems with elastic elements either in parallel with the main actuator as in (21.23), or in series as in

$$f(\ddot{q}, \dot{q}, q, t) = -\mathbf{K}(q - \theta) \quad (21.26)$$

$$\mathbf{B}\ddot{\theta} = \mathbf{K}(q - \theta) + \tau, \quad (21.27)$$

where \mathbf{B} represents the constant inertia matrix of the main motor part of the model. The objectives of [21.117] were extended to compute the optimal value of a constant stiffness for minimizing energy consumption in a periodic task for series configuration, and both the optimal stiffness and spring preload values for the parallel case.

Assuming that $\mathbf{K} = \text{diag}(K_j)$ and $\mathbf{B} = \text{diag}(B_j)$ (the second assumption is required in the serial case) it is shown how to derive expressions of the optimal actuation parameters for minimizing energy-related cost functions such as (21.24) and

$$\mathbf{J}(\mathbf{K}) = \int_{iT}^{iT+T} \mathbf{w}_d(\mathbf{K}, t)^T \mathbf{w}_d(\mathbf{K}, t) dt. \quad (21.28)$$

where $\mathbf{w}_d(\mathbf{K}, t) = \tau_d(\mathbf{K}, t) \cdot \dot{\theta}_d(\mathbf{K}, t)$, with \cdot^* denoting element-wise multiplication. Rather surprisingly, it is shown in [21.121] that it is possible to save lengthy iterations and simulations by computing analytical expressions for the optimal stiffness and preload as integral functions of any given desired joint trajectories: for example, the series stiffness that minimizes the cost (21.24) is given by the formula

$$\mathbf{K}_j^* = \frac{\int_{iT}^{iT+T} \mathbf{B}_j^2 \ddot{f}_j(\ddot{q}_d, \dot{q}_d, q_d, t) dt}{\int_{iT}^{iT+T} \mathbf{B}_j \ddot{f}_j(\ddot{q}_d, \dot{q}_d, q_d, t) (\mathbf{B}_j \ddot{q}_{d,j} + f_j(\ddot{q}_d, \dot{q}_d, q_d, t)) dt}. \quad (21.29)$$

21.7.2 Controlled Oscillatory Dynamics

The basic idea to generate periodic motions is here to control the output of the joint such that it behaves like a desired, oscillatory dynamic system rather than imposing a predefined, time-dependent trajectory [21.118]. The resulting motion will be therefore depending on initial conditions and possible perturbations, but will eventually converge to the periodic orbit. For simplicity, here we describe the concept for the

model of a single variable stiffness actuated joint, satisfying

$$m\ddot{q} + \frac{\partial V_\tau(\theta, q)}{\partial q} = 0. \quad (21.30)$$

The output position of the joint is denoted $q \in \mathbb{R}$ and the velocities $\dot{\theta} = u \in \mathbb{R}^2$ of the two actuators of the VIA joint are assumed as control inputs. Note that this model corresponds to the first row in (21.9) with $m = 2$ and $n = 1$. Let us assume a generic family of desired oscillatory dynamics

$$\ddot{q} + a(q) = 0, \quad (21.31)$$

with $a(q)$ chosen such that a periodic orbit results. In particular, $a(q)$ can be the derivative of a desired potential function $V_d(q)$. The goal is to control the system (21.30) such that

$$h(\theta, q) = a(q) - \frac{1}{m} \frac{\partial V_\tau(\theta, q)}{\partial q} = 0 \quad (21.32)$$

holds. With initial conditions $(q(0), \dot{q}(0), \theta_1(0), \theta_2(0)) \in h(0)^{-1}$ the constraint (21.32) can be fulfilled, if the control u satisfies the constraint on velocity level, that is, $\dot{h}(\theta, q) = 0$. Since $\dot{\theta} = u$ is the control input, this implies

$$\dot{h}(\theta, q) = -\mathbf{A}(\theta, q)u + b(\theta, q, \dot{q}) = 0, \quad (21.33)$$

with

$$\mathbf{A}(\theta, q) := \frac{1}{m} \frac{\partial^2 V_\tau(\theta, q)}{\partial q \partial \theta}, \quad (21.34)$$

$$b(\theta, q, \dot{q}) := \left(\frac{\partial a(q)}{\partial q} - \frac{1}{m} \frac{\partial^2 V_\tau(\theta, q)}{\partial q^2} \right) \dot{q}. \quad (21.35)$$

Using a generalized right inverse \mathbf{A}^\dagger of the matrix \mathbf{A} , the control

$$u = \mathbf{A}(\theta, q)^\dagger b(\theta, q, \dot{q}), \quad (21.36)$$

fulfills the velocity constraint (21.33).

The solution of (21.33) with regard to u is not unique, as the problem is under-constrained. By choosing a particular generalized pseudoinverse of \mathbf{A} of the form $\mathbf{A}^\dagger = \mathbf{B}^{-1} \mathbf{A}^T (\mathbf{A} \mathbf{B}^{-1} \mathbf{A}^T)^{-1}$, the solution (21.36) minimizes the norm $\|u\|_{\mathbf{B}}^2$ with respect to a certain metric tensor \mathbf{B} . If, for example, \mathbf{B} is the matrix containing the motor inertias then the kinetic energy of the actuators is minimized. The under-constrained situation can be interpreted such that the desired motion might be achieved by both adjusting the stiffness and the motor position of the actuators. Choosing a certain metric \mathbf{B} implicitly defines a weighting of the two components.

21.7.3 Exciting Intrinsic Oscillatory Dynamics

Exciting the intrinsic oscillatory behavior of mechanical systems, that consist of kinetic and potential energy storages, is inspired by the concept of resonance from linear oscillation theory. The idea is to move the actuators of the compliant system such that the trajectory of link variables is periodic and thereby the energy input due to the motor motion ideally counteracts only the loss of dissipated energy. Instead of tracking an arbitrary trajectory, here we are interested in exciting intrinsic resonant motions of the system.

Consider the dynamical system of the form (21.10). The objectives in this section are finding a control τ_m such that for a certain period T , the trajectories of link variables fulfill $\mathbf{q}(t+T) = \mathbf{q}(t)$, and the intrinsic oscillatory dynamics are exploited to the maximally possible extent. Assuming that the motion $\mathbf{q}(t)$ should take place on one of several one-dimensional manifolds $\mathcal{Z}_j \subset \mathbb{R}^n$ (referred to as oscillation modes), the problem can be further refined:

- C1: Given the mapping $\mathbf{z} = \mathbf{z}(\mathbf{q})$. If z_j represents the coordinate of the desired oscillation mode, then the control must ensure that oscillations excited in all other modes decay, that is, for $i \neq j$, $\dot{z}_i \rightarrow 0$.
- C2: The motion of z_j has to be controlled to sustain a periodic motion with a desired oscillation amplitude.

21.7.4 Model-Based Approach

To derive a coordinate transformation $\mathbf{z} = \mathbf{z}(\mathbf{q})$ and to fulfill the above conditions, the free motion ($\tau_{\text{ext}} = \mathbf{0}$) link-side dynamics of (21.10) can be modified by first considering $\boldsymbol{\theta}$ as control input, that is,

$$\boldsymbol{\theta}_d = \mathbf{q}^* + \mathbf{K}_p^{-1}(\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) - \mathbf{K}_D\dot{\mathbf{q}} + \boldsymbol{\gamma}), \quad (21.37)$$

with $\boldsymbol{\gamma}$ being a decoupling term to be specified later. This leads to the closed-loop dynamics

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{K}_p(\mathbf{q} - \mathbf{q}^*) + \mathbf{K}_D\dot{\mathbf{q}} = \mathbf{0}. \quad (21.38)$$

In order to excite oscillations which are quite close to the initial oscillation modes, consider coordinates z_i which correspond to the instantaneous modal coordinates $\mathbf{z} = \mathbf{Q}(\mathbf{q})^{-1}(\mathbf{q} - \mathbf{q}^*)$. $\mathbf{Q}(\mathbf{q})$ is defined on the basis of double diagonalization of \mathbf{M} and \mathbf{K} such that $\mathbf{Q}(\mathbf{q})^{-T}\mathbf{Q}(\mathbf{q})^{-1} = \mathbf{M}(\mathbf{q})$ and $\mathbf{Q}(\mathbf{q})^{-T}\text{diag}(\boldsymbol{\lambda}(\mathbf{q}))\mathbf{Q}(\mathbf{q})^{-1} = \mathbf{K}_p$, where $\boldsymbol{\lambda}(\mathbf{q}) \in \mathbb{R}_{>0}^n$ are generalized eigenvalues, as proposed in [21.120]. By considering a damping

design

$$\mathbf{K}_D = 2\mathbf{Q}(\mathbf{q})^{-T}\text{diag}\left[\xi_i\sqrt{\lambda_i(\mathbf{q})}\right]\mathbf{Q}(\mathbf{q})^{-1},$$

and by choosing $\boldsymbol{\gamma}$ as

$$\boldsymbol{\gamma} = [\mathbf{M}(\mathbf{q})\ddot{\mathbf{Q}}(\mathbf{q}) + \mathbf{K}_D\dot{\mathbf{Q}}(\mathbf{q})]\mathbf{z} + 2\mathbf{M}(\mathbf{q})\dot{\mathbf{Q}}(\mathbf{q})\dot{\mathbf{z}}, \quad (21.39)$$

the resulting closed-loop dynamics

$$\ddot{z}_i + 2\xi_i\sqrt{\lambda_i(\mathbf{q})}\dot{z}_i + \lambda_i(\mathbf{q})z_i = 0$$

fulfills the condition C1, if for $i \neq j$, $\xi_i > 0$. Then, the nonlinear damping term

$$\xi_j = -\frac{\dot{\lambda}_j(\mathbf{q})}{4\lambda_j(\mathbf{q})^{\frac{3}{2}}} + \frac{1}{2}\sqrt{\lambda_j(\mathbf{q})}k_H[H(\mathbf{q}, z_j, \dot{z}_j) - H_d]$$

produces a periodic motion $z_j(t+T) = z_j(t)$. In particular, the resulting limit cycle corresponds to a level H_d of the energy function $H(\mathbf{q}, z_j, \dot{z}_j) = \frac{1}{2}(\frac{1}{\lambda_j(\mathbf{q})}\dot{z}_j^2 + z_j^2)$ as proposed in [21.122].

Note that applying the control (21.37) to the system (21.10) requires a controller that ensures a tracking $\boldsymbol{\theta}(t) \rightarrow \boldsymbol{\theta}_d(t)$ of the desired motor position $\boldsymbol{\theta}_d(t)$.

21.7.5 Model-Free Approach

Exciting oscillations in multi-DOF mechanical systems without changing at all the original inertia and stiffness properties of the plant requires either an ideally separated excitation on a certain oscillation mode or intrinsic physical damping properties that ensure the decay of oscillations excited in the other modes cf. condition C1. Note that in most cases fully decoupled modes do not even exist. On the basis of the latter assumption, which is valid in biological systems and some robotic examples [21.123], the control law

$$\Delta\boldsymbol{\theta}_z = \begin{cases} \text{sign}(\tau_z)\hat{\boldsymbol{\theta}}_z & \text{if } |\tau_z| > \epsilon_{\tau_z} \\ 0 & \text{otherwise} \end{cases} \quad (21.40)$$

excites a modal oscillation in a simple way. Thereby, the linear transformation $z_j = \mathbf{w}^T\mathbf{q}$ approximates the nonlinear mapping $\varphi: \mathbb{R}^n \rightarrow \mathcal{Z}_j$, such that the generalized modal force can be transformed by the vector of weights $\mathbf{w} \in \mathbb{R}^n$, that is,

$$\tau_z = \mathbf{w}^T(\boldsymbol{\psi}(\boldsymbol{\theta} - \mathbf{q}) - \boldsymbol{\psi}(\boldsymbol{\theta}^* - \mathbf{q}^*)), \quad (21.41)$$

where $\boldsymbol{\theta}^*$ and \mathbf{q}^* satisfy the equilibrium conditions $\mathbf{g}(\mathbf{q}) + \boldsymbol{\psi}(\mathbf{q} - \boldsymbol{\theta}) = \mathbf{0}$. When the modal force τ_z exceeds a certain threshold ϵ_{τ_z} , the controller switches by an

amplitude $\hat{\theta}_z$. This results in steps of desired motor positions

$$\theta_d = \theta^* + w \Delta \theta_z.$$

Since the motor positions θ are not the control input of the system (21.10), a motor PD controller should be considered to ensure that $\theta(t) \rightarrow \theta_d(t)$.

Note that the oscillation controller requires neither derivatives of measured signals nor model knowledge

21.8 Optimal Control of Soft Robots

Robot joints with intrinsic elasticity have some major advantages over their rigid counterparts: they are more robust, versatile, and can store energy. These properties enable robots to realize motions which would not be possible using stiff actuators of the same size. However, the question remains open as to how elastic elements in soft robots can be best controlled to exploit their potential. Optimal control (OC) theory is being regarded as one of the most promising tools to clarify such questions: as far as an appropriate choice of the cost functional is available, optimal control techniques can provide design guidelines for both the physical design and the control of soft robots.

There are at least two main reasons why OC is fundamental to study soft actuators. On one side OC provides an absolute performance reference that factorizes the control design out of the equation, hence it furnishes a principled basis to compare the performance of different system designs. On the other side, OC is a key element in understanding planning and control methodologies for soft actuators. A careful analysis of OC results obtained through either analytic or numerical techniques, allows to distillate laws summarizing control policies that can be applied to classes of tasks.

General analytic solutions could be developed so far only for one-DOF joints. Physical bounds on states and inputs, the strong nonlinear structure of the robots and the high number of DOF allow only numerical solutions for general robotic systems. Nevertheless, choosing an advantageous parametrization for numerical solutions of the OC problem strongly benefits from insights given by the low-dimensional analytical solutions. Therefore, the analytical concepts are explained for some basic examples in this section.

21.8.1 OC Theory

We consider the dynamics of a system described in standard form ($\dot{x} = f(u, x, t)$), with the cost functional J consisting of a terminal cost ϑ and an

of the plant. Therefore it is simple and robust, and can be easily applied to different types of compliantly actuated systems. The control law is, at least for the one-DOF case, the optimal solution for maximizing the oscillation amplitude in minimum time. Furthermore, the control law defined by (21.40) and (21.41) is plausible to have a biological equivalent, since it strongly resembles the computation function of neurons.

integral cost L

$$J(u) = \vartheta(x(t_f), t_f) + \int_{t_0}^{t_f} L(x, u, t) dt. \quad (21.42)$$

According to Pontryagin's minimum principle [21.124], the optimal control u^* is known to minimize the Hamiltonian function $\mathcal{H} = \lambda^T f(u, x, t) + L$, along the optimal trajectory, where λ are the costates. For an OC problem with constraints on only the control $u \in \mathbb{U}$, differential equations of these costates are given by $\dot{\lambda} = -\partial \mathcal{H} / \partial x$. Furthermore, if the final state is not explicitly stated, Minimum Principle also provides boundary conditions for λ at the final time

$$\lambda(t_f) = \frac{\partial \vartheta}{\partial x} \Big|_{t_f}.$$

In order to make use of the Minimum Principle, one has to first solve these differential equations for x and λ and then find the control u^* , which minimizes the Hamiltonian: $\mathcal{H}(x^*, \lambda^*, u^*) \leq \mathcal{H}(x^*, \lambda^*, u)$ for all $u \in \mathbb{U}$, where x^* and λ^* denote the optimal states and costates.

21.8.2 SEA Optimization

Naturally, the performance achievable with a given soft actuator under optimal control depends on the physics of the actuator itself. It is therefore very interesting to study the nested optimization problem of how to design soft robotics actuators which can produce the best performance under optimal control.

From the analysis of a one-DOF SEA joint, it can be observed [21.17] that there exists an optimal value of the linear stiffness that maximizes the (optimally controllable) peak speed. The optimal stiffness value depends on the motor (e.g., maximum acceleration and speed) and on the task (e.g., terminal time). This result is illustrated in Fig. 21.12.

21.8.3 Safe Brachistochrone OC Problem

One of the first instances of use of OC for soft (variable stiffness) robots is the study of the so-called *safe brachistochrone* problem [21.125]. The goal was to find control laws for the equilibrium position and variables transmission stiffness such that a point-to-point link motion is achieved in minimum time subject to a limit on the worst-case impact force that the link could exchange with the environment during the trajectory. Limiting the impact force during motion can be useful both for increasing the safety of a robot operating in proximity of humans, and for reducing the risk of damaging the robot itself in accidental collisions with a stiff environment. The main results were to show that VSAs can perform better (that is, faster within bounds on a measure of impact risk) than both conventional (rigid) actuators and SEAs, and that the optimal stiff-

ness law is inversely related to the link velocity, in a fashion roughly described by the easy-to-remember rule *fast and soft, stiff and slow*.

21.8.4 Max Speed OC Problem

A complementary example of application of OC theory concerns the problem of maximizing the velocity of an elastic robot joint at some desired final time or position. This goal is relevant to impulsive tasks, such as jumping on feet, hitting a ball or hammering a nail. Conversely to the previous example, in such tasks it might be desirable that impact is maximized: indeed, it turns out that elastic actuators are neither intrinsically more or less safe than rigid joints, but can be both, under suitable control laws.

The differential equations for the states and costates of this OC problem are summarized in Table 21.1. Note that the functional J to be minimized consists merely of a terminal cost $J(u_1) = -\dot{q}(t_f)$. For this particular problem, studied in [21.126, 127], the condition of minimizing the Hamiltonian \mathbb{H} on the optimal trajectory becomes $u_1^* \lambda_1^* \leq u_1 \lambda_1^*$, for all $u_1 \in [u_{1\min}, u_{1\max}]$. Consequently, u_1^* will have its minimum or maximum value depending on the sign of the first costate λ_1^* . Using Table 21.1, this first costate can be obtained as $\lambda_1^* = -\omega \sin[\omega(t_f - t)]$, where ω denotes the natural frequency of the system. The optimal control u_1^* will thus be periodic with the eigenfrequency of the system ω and take its maximum (minimum) value, whenever $\sin[\omega(t_f - t)]$ is positive (negative). Note that the switching of the optimal control occurs with the eigenfrequency starting from the final time backward. For the particular case

Fig. 21.12 Optimal motor velocity ($\omega = 5 \text{ rad/s}$, $|u_{1\min}| = u_{1\max} = 1 \text{ rad/s}$)

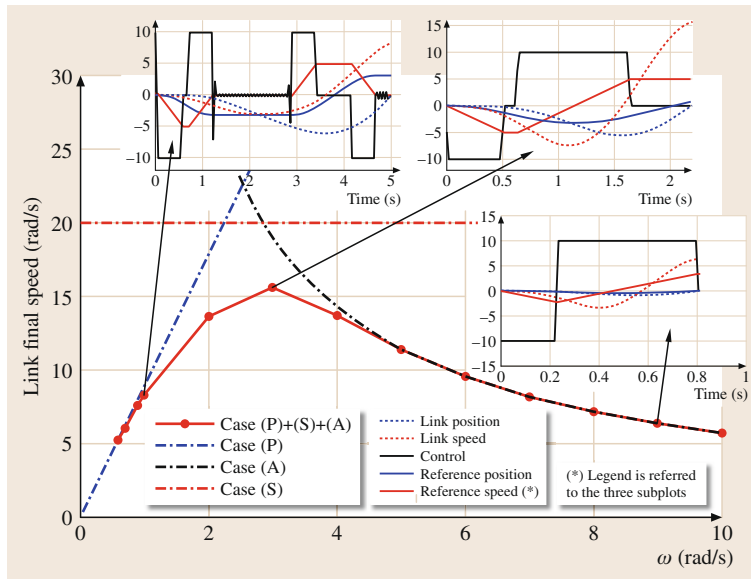

Fig. 21.13 Diagram (after [21.17]) representing the maximum speed reached by a one-DOF SEA after a single swing at varying the spring stiffness ($\omega = \sqrt{k/m}$). Dashed curves show terminal speed $\dot{q}(T)$ under ideal motor position control (case P), speed control (case S) and acceleration control (case A). The continuous red curve shows terminal speed in the realistic condition of motor acceleration control ($|\ddot{\theta}(t)| \leq 10 \text{ rad s}^{-2}$), with bounds on position ($|\theta(t)| \leq \pi \text{ rad}$) and velocity ($|\dot{\theta}(t)| \leq 5 \text{ rad s}^{-1}$). The small charts show optimal control and state patterns in time

Table 21.1 OC problem for the elastic joint ($\omega = \sqrt{\frac{k}{m}}$)

Excitation	States x	Cost J	$\dot{x} = f(x, u_1)$	$\dot{\lambda} = -\frac{\partial \mathbb{H}}{\partial x}$	$\lambda(t_f)$
$u_1 = \dot{\theta}$	$\begin{pmatrix} \phi \\ \dot{q} \end{pmatrix}$	$-x_2(t_f)$	$\begin{pmatrix} u_1 - x_2 \\ \omega^2 x_1 \end{pmatrix}$	$\begin{pmatrix} -\omega^2 \lambda_2 \\ \lambda_1 \end{pmatrix}$	$\frac{\partial \mathbb{H}}{\partial x} \big _{t_f} = \begin{pmatrix} 0 \\ -1 \end{pmatrix}$

when the final time is a multiple of the oscillation period $t_f = nT = 2\pi n/\omega$, switching can be equivalently done in feed-forward after every half period. For an elastic joint starting from the rest position, this particular control law states then to switch the motor velocity when the angular deflection ϕ or similarly the acceleration of the system changes its sign

$$\dot{\theta}^* = \text{sign}(\ddot{q})u_{1 \max} . \quad (21.43)$$

If an additional quadratic integral cost in the control, $L = cu_1^2$ with a positive scalar c , is considered in (21.42), a continuous control law will follow. For $t_f = nT$ a classical resonance excitation with a sinusoidal input then follows, corresponding to intuition and knowledge of linear systems. It is possible to extend these analytical solutions for nonlinear stiffness characteristics and damped systems [21.127]. For example, for an underdamped robotic link a similar optimal control is found, which is periodic with the damped eigenfrequency. Different motor models can also be investigated analytically.

21.8.5 VSA Optimization

The very fact that for different tasks the optimal value of stiffness is different implies that the adaptability of the physical stiffness of actuators can be very useful in improving performance over a set of tasks.

One further interesting question is raised by the possibility offered by VSA technologies to vary the actuator stiffness in time. The problem becomes that of finding the optimal time course of both the actuator position $\theta(t)$ and stiffness $k(t)$ so as to maximize performance. This problem can be again investigated using OC theory [21.17, 128]. Without going in the details of OC computations, results show that under the simplifying assumption that the actuator position and stiffness are bounded but can be changed instantaneously, the optimal control for a single swing and free terminal time (within this swing) is bang–bang: the optimal reference position is

$$\theta^* = \text{sign}(\dot{q})\theta_{\max} ,$$

while the optimal stiffness $k^*(t)$ takes its minimum value k_{\min} or maximum value k_{\max} depending on the

switching function

$$k^* = \begin{cases} k_{\min} & \text{if } \dot{q}\ddot{q} < 0 \\ k_{\max} & \text{if } \dot{q}\ddot{q} > 0 \end{cases} , \quad (21.44)$$

while for $\dot{q}\ddot{q} = 0$ the stiffness value can be set arbitrarily. This indicates the rather intuitive notion between link velocity and accelerations summarized by

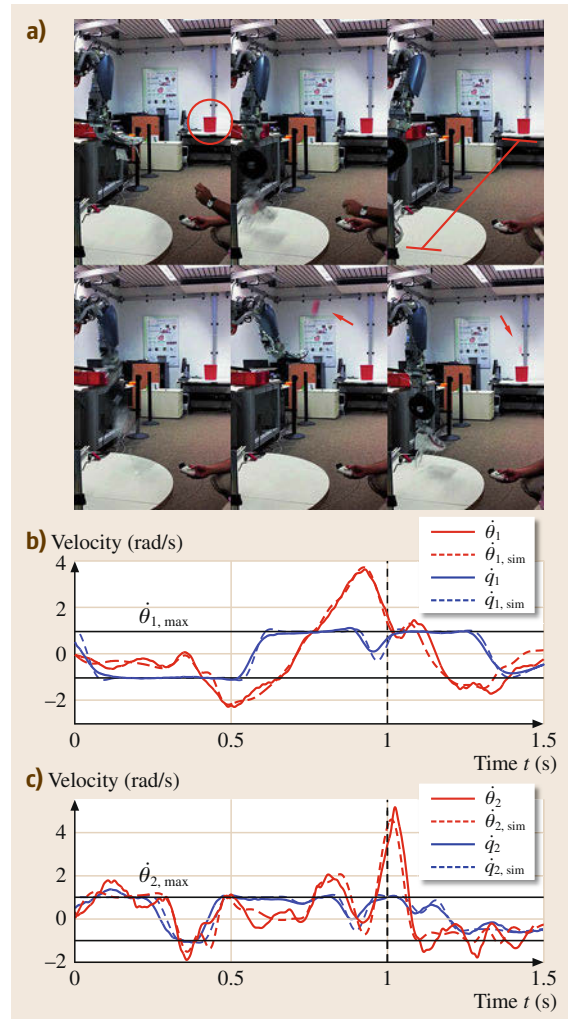

Fig. 21.14a–c Throwing experiment with the DLR hand-arm system (after [21.87]). (a) Experimental setup, (b) velocity of joint 1, (c) velocity of joint 2

the rule *stiff speed-up, soft slow-down*. More general cases of VSA optimization are discussed in [21.17, 128] and [21.126]. It is important to notice that even for one-link robots analytical solutions are not always straightforward to find, especially if state constraints exist or system properties have nonlinearities.

Under some conditions, it may be possible to apply efficient numerical solutions to such problems. For instance, if the soft actuator dynamics system are linear (as e.g., in the SEA case) but there exist state and control constraints (e.g., the torque-speed characteristic of a dc motor), it is possible to translate the optimal control problem into a convex optimization problem [21.129], for which there exist fast and reliable methods to obtain the global solution. For robots with multiple-links, differential equations re-

sulting from OC theory are nonlinear and cannot in general be solved analytically. Consequently, numerical methods such as pseudospectral methods [21.130] or iterative linear quadratic regulator (ILQR) methods [21.131, 132] are employed for these systems. One example of how to use these methods to outperform rigid robots is described in [21.133], where a throwing motion is optimized using the gauss pseudospectral method [21.134]. The reported experiments verify the system's ability to use the elastic energy for explosive motions. Figure 21.14a illustrates the experimental setup, while the motor and link velocity are depicted on Fig. 21.14b,c. Note that the link velocities \dot{q} reach more than double the maximum motor velocities $\dot{\theta}_{\max}$ during the motion, which would be clearly not possible with stiff actuators.

21.9 Conclusions and Open Problems

In this chapter, we have reviewed some of the technologies and methods for analysis and control underpinning the use of novel actuators for soft robotics. The field has rapidly expanded in recent years, and it is very difficult to provide an exhaustive up-to-date account of all innovations being continuously brought forward: hopefully, this chapter provides at least a faithful picture of some of the most important current research trends in soft actuation.

When comparing current robots with biological systems in terms of actuator energy density, energy efficiency of motion, resilience, and sensitivity during interaction, the importance of intrinsic compliance becomes striking. We are still far from having found so far the optimal technical realization of compliant, muscle-like actuators regarding design simplicity, integration, and energy density. Nevertheless, in this chapter foundations have been described both by properly defining basic notions such as nonlinear impedance and addressing parametric identification, and in analyzing and standardizing the main physical properties to be used for the description of elastic actuators. A widely agreed set of characteristic parameters summarized in a standardized data sheet format [21.75–77] help comparing the very heterogeneous design approaches and choosing the best concept for a given application. We proposed a quite general dynamic model for flexible robots with lumped elasticities, covering all designs proposed to our knowledge so far. The model is obviously related to the models of flexible robots from Chap. 11 and can be regarded as a generalization thereof. The control of flexible robots was focused on two main challenges. First, the simultaneous control of the position and in-

trinsic impedance of the devices has to be solved. This is a challenge for systems with highly nonlinear and very compliant behavior. This aspect was addressed on joint and the Cartesian level.

Second, control to push flexible robots to their limit and maximally exploit their potential benefits. If robustness comes mainly by the design process, that is not true for energy efficiency and performances maximization (even under safety constraints). The achievement of these features requires optimization and optimal control algorithms, such as those exposed in the present chapter. Moreover, OC algorithms can be used as a tool for comparison among different actuator designs extracting their inherent (i.e., control-independent) performance boundaries, and to derive easy-to-understand control rules for peculiar DOFs (e.g., stiffness) of soft robots.

Important new directions are open in front of the research community. On one side, new active materials could provide a boost to the development in soft robotics actuators, especially in the small scale; on the other hand, it can be expected that some of the promising advanced material research in the past will eventually make their way in practically viable technologies. New functional architectures for actuators that can adapt their physical behavior to the task are also potentially very fruitful. An important future trend is the extension from *variable stiffness* to VIAs, capable of more closely mimicking the functionalities of muscular structures where not just the elasticity, but also the damping (and perhaps the effective inertia) can be physically tuned. Much work remains also to be done in the understanding of the theoretical underpinnings and in practical methods for the identification and

control of nonlinear, time varying, multidimensional impedance.

The very fact that research in novel actuators for soft robotics has produced a wealth of ideas and solutions poses a challenge of different nature. Indeed, a huge potential for innovation is already available to researchers and practitioners, which has been only superficially tapped so far in applications. Soft actuators could change the landscape not only in robust and safe interaction or in locomotion: there are probably many, more specific application niches where the new technologies could have an impact – possibly also outside the scope of *robotics* narrowly defined, in the larger domain of *automation*. To foster technological awareness of soft robotics potential in the community of those interested in machines that can

move and interact more naturally, several initiatives are being undertaken, including an IEEE technical committee on soft robotics [21.135] and several workshops, special issues and even specialized journals on the topic. Recently, a natural machine motion initiative (NMMI) [21.136] has been launched with the aim of diffusing the ideas of soft actuation to achieve *naturally moving* robots with human-like grace, power, and dexterity. One of the objectives of the NMMI is to make the technology of soft actuators widely available to the general public, by publishing as open-source the design and all instructions needed to build and use low-cost actuators, thus building a community of developers interested in sharing advances toward simple, affordable, yet smooth, strong, and accurate muscles for robots.

I-Ming Chen, Mark Yim

This chapter presents a discussion of modular robots from both an industrial and a research point of view. The chapter is divided into four sections, one focusing on existing reconfigurable modular manipulators typically in an industry setting (Sect. 22.2) and another focusing on self-reconfigurable modular robots typically in a research setting (Sect. 22.4). Both sections are sandwiched between the introduction and conclusion sections.

This chapter is focused on design issues. Rather than a survey of existing systems, it presents some of the existing systems in the context of a discussion of the issues and elements in industrial modular robotics and modular robotics research. The reader is encouraged to look at the references for further discussion on any of the presented topics.

22.1	Concepts and Definitions	531
22.1.1	Concept of Modularity	532

Modularity in design engineering refers to a compartmentalization of elements. Most often modularity in complex systems occurs as a result of taking a complex system and dividing it into pieces in order to better understand the simpler elements and parallelize the design efforts. Modularity also facilitates the replacing of elements either for repair or upgrading new functionality. The alternative to a modular approach is an integrated approach where systems are designed as

a whole. While integrated approaches tend not to be as easy to repair, upgrade or reconfigure, they do have fewer constraints on element design and therefore can be made more optimal. Integrated approaches can focus on lowering cost or having higher performance. In mechanical devices, the choice between modular or integrated architectures can have a large impact on the range of application as well as cost or performance [22.1].

to screwing bolts or buffing surfaces. For robotics, the same impact applies. However, robots have an inher-

ent complexity that lends itself to modularity, such as actuator modules, sensor modules, and sometimes computation modules. In the following sections, definitions will be given for different kinds of modularity frequently seen in robotics.

22.1.1 Concept of Modularity

The product design literature can be looked at as encompassing robotics – which can be considered as an industrial or research product. The architecture of product modularity can be categorized into three subtypes: slot, bus, and sectional modularity [22.1]:

- **Slot architecture:** Each of the interfaces between components is of a different type from the others, so that the various components in the product cannot be interchanged.
- **Bus architecture:** There is a common bus to which the other physical components connect via the same type of interface.
- **Sectional architecture:** All interfaces are of the same type and there is no single element to which all the other components attach, i.e., there is no base component. The assembly is built up by connecting the components to each other via identical interfaces (Fig. 22.1).

Such classifications provide a good definition of modular robots as follows:

- If a complex robotic system adopts a slot- and bus-modularity design approach for its internal structure and architecture, not the external configuration, it can be called a *modularly designed robotic system* benefiting from design parallelization. Such a robot may have a unified and integrated configuration that cannot be changed from outside.
- If a robot adopts a bus- and sectional-modularity design approach for both internal structure and external configuration, it can be called a *modular robot*. The users can reconfigure the compartmentalization and interchange functional modules with some level of effort.

22.1.2 Definition and Classification of Modular Robots

Any system can be reconfigured by destructing and reconstructing it, for example in the worst case, using a blowtorch and milling machine. The key element we must define is the level of effort required to reconfigure. We propose here three levels from the lowest to the highest level of effort of the user:

1. The system reconfigures itself. It is *self-reconfigurable*.
2. The system is reconfigured by a lay user with or without special tools typically in matter of seconds to minutes.
3. The system is reconfigured only by an expert with specialized tools.

This chapter will focus on modular robots that give rise to *plug-and-play* reconfiguration of the system for task and function changes, levels 1 and 2. Level 1 systems are self-reconfigurable systems with sectional modularity. Level 2 systems in this chapter focuses on reconfigurable modular manipulators with a finite set of modules of different functions.

The modular manipulator type of robotic systems are natural evolution of industrial robot manipulators that consist of a number of specific functional modules, such as actuator modules, link modules, and end-effector modules. Subsequently, robots with the serial and branching topology, such as humanoid robots, legged robots, mobile manipulators adopt a similar approach for modularity as these functional modules form the basis of a robotic system.

The self-reconfigurable modular robots grew out of the concept of self-evolution and self-configuration of biological cells with identical units. Such a robot normally consists of a large number of a small set of types of mechatronic units that possess actuation, connection, communication, and computing capability that can be assembled together in arbitrary forms and also reconfigure itself.

Although the two types of modular robots originated from different fundamental concepts, the goals to provide a large number of possible robot configurations for different tasks with the same set of basic robot modules are the same.

22.2 Reconfigurable Modular Manipulators

Reconfigurable modular manipulators are robot arms that have elements that can be rearranged.

22.2.1 Background of Modular Manipulator Systems

The simplest form of modular manipulator comes in the form of automatic tool changers also called quick-change end-effectors. These are optional tools that can be attached to the end of a robotic arm. Automatic tool changers are standard equipment for many **CNC** (computer numerically controlled) milling machines and lathes since the 1960s. They enable the machines to drill holes of different sizes, or cut different shapes. Although **CNC** machines are not often considered industrial robots, they share the same elements (actuators, sensors, and computation) and their function is more limited. Most industrial robot arms can be equipped with automatic changing end-effectors by adding a wrist that has the compatible interface for a variety of grippers and end-effectors. These devices are available commercially from Schunk (Germany), ATI industrial automation (USA), Destaco, Amatrol, RE2 (USA), RAD, and others.

In the modularization of industrial robots, the granularity of the components is usually based on their basic functions, i.e., motion actuation and tooling. Thus, the design of modules is highly differentiated into actuator modules, passive joint modules, and tooling modules, etc. Several prototype modular robotic systems have been built and demonstrated, including the reconfigurable modular manipulator system (**RMMS**) [22.2], several generations of the cellular robotic system (**CEBOT**) [22.3], and modular manipulator systems developed by University of Toronto [22.4], University of Stuttgart [22.5], University of Texas at Austin [22.6], and Toshiba Corp. [22.7].

Basically, these systems have serial-type (or open-chain) geometry with large working envelopes. These serial-type modular robots are well suited for assembly, trajectory tracking, welding, and hazardous material handling. Parallel modular robots have also been developed for light-machining tasks [22.8]. As indicated in [22.8], modular design can reduce the development cycle of the parallel robots significantly. Furthermore, it allows a trial-and-error approach for the construction of parallel robots that is impossible with the integrated design approach.

With globalization of world manufacturing, the concept of modular manipulators has quickly gained industrial attention. A full-scale reconfigurable robotic system workcell consisting of three modular robots

with a total 15 axes was successfully showcased in 1999 [22.9] (Fig. 22.2). The modular robot workcell has a serial type 6-degrees-of-freedom (**DOF**) robot for the pick-and-place action of the work piece, a 2-**DOF** robot for work piece transfer, and a 6-**DOF** parallel robot for milling operations on the work piece. All the robots are built from the same set of modular components, including actuator modules, link modules, and tool modules.

The German company Amtec, later acquired by Schunk, developed the first commercially available modular manipulator system called PowerCube. Schunk has subsequently developed its industrial manipulators and automation systems based on PowerCube with some success [22.10]. Today there are many robotic systems with a wide spectrum of applications that are built around modular robot components.

The modular robot concept also proliferated in the hobby and educational robot sectors around the year 2000 by the introduction of well-packaged self-contained servo motor modules into inexpensive robotic devices, such as Robotis (Korea) and Kondo (Japan), as well as Lego (Denmark) and other toy companies making educational robots.

Mobile robots with legs, wheels, and tracks also belong to this class of modularity where they are configured for different task requirements such as those needed for disaster relief, rescue, and surveillance purposes. Two tracked modular mobile robots designed with multiple track segments [22.11] and reconfigurable tracks allowing serial and parallel connections [22.12] have been demonstrated. The work in [22.13] contains an in-depth review of the development in modular mobile robots.

Fig. 22.2 15-axis Reconfigurable Robotic Workcell (after [22.9])

22.2.2 Module Design Issues

A modular robot consists of the two main features found in a modular product: 1) a one-to-one mapping from functional elements to the physical components of the product and 2) decoupled interfaces between the components of different modules [22.1]. For modular manipulators, the essential components are the base, positioning, and orienting mechanisms composed by actuator modules and link modules of different dimensions and geometry, and the end-effector module. For legged and wheeled mobile robotic systems, the motion generation mechanism modules are essential.

The actuator modules normally use DC or AC motors as a 1-DOF rotate or pivot joint module typically with compact high reduction ratio transmission mechanisms [22.2, 4, 6, 7, 9]. Some modular systems also adopt 1-DOF linear modules for larger workspace envelope [22.4, 9] and 2-DOF joint modules for compact dexterous motions [22.10]. The actuator module shown in Fig. 22.3 has two independent linear and rotary motion capabilities suitable for compact assembly tasks [22.9]. The actuator modules are typically designed with similar geometry but with different dimensions and power ratings for different application requirements.

The link modules connecting units in between the actuators function as reachable workspace extenders. Some systems adopt a standard fixed-dimension connection module [22.3, 4, 6] and some use variable dimension modules that can be customized to satisfy arbitrary design constraints [22.9]. In some systems [22.2],

the link module becomes part of the actuator module so that the module acts as an actuator as well as the connecting structure.

22.2.3 Interface Design Issues

The mechanical connecting interface between modules in a modular manipulator needs to satisfy three basic requirements:

1. Stiffness
2. Fast reconfiguration
3. Interchangeability.

Thus, the design of mechanical connections or docking mechanisms is a critical issue. In a fully or semisupervised robotic system, like some modular manipulator systems [22.2–9], the connecting mechanism is designed to be manually operated for reliability and safety reasons. In a fully autonomous system, the connecting mechanism needs to be designed typically with an extra actuator and locking mechanism for carrying out the connection automatically. This is the case for most of the self-reconfigurable modular robots.

In order to meet the requirement of interchangeability, the electronic and communication interface for the modular system normally adopts common communication network architecture with plug-and-play capability similar to local area network (LAN). There are a number of existing industrial standard network protocols for real-time robot control suitable for such applications, like CAN-bus, RS485, and IEEE 1394. The progressive development of industrial automation protocols will facilitate the implementation of modular robot communications. While many of the early systems use wired multidrop bus architectures for communications, multirobot systems have used fast local message forwarding [22.14] and wireless networking.

22.2.4 Modeling of Modular Manipulators

Challenges to model the modular manipulator systems come from the lack of uniform formalisms of the unfixed robot configuration and geometry and the errors accumulated from assembly and dis-assembly of the modules. Hence, the first effort in modular robot modeling was the introduction of a graph-based technique with additional module assembly information for the representation of a modular robot configuration [22.15]. This work introduced a modular robot representation scheme, termed assembly incidence matrix (AIM) for distinct modular robot configurations. There are several subsequent extensions and variations of AIM for broader categories of modular robots including modular mobile manipulators [22.16–18].

Fig. 22.3 A 2-DOF translate-turn module with ball-screw and ball-spline mechanism

Once the modular robot configuration can be distinctly defined with the type of modules, the connection sequence, module orientation, kinematic, and dynamic models of the robot can be obtained through an automatic generation algorithm [22.19]. Kinematic model generation can be achieved through the conventional Denavit–Hartenberg (DH) parameterization [22.2–4, 17] or the coordinate-free local product-of-exponential (POE) approach [22.8, 9, 19]. However, the DH method does not provide a clear distinction between the arranging sequence of modules in a robot chain, and it is an initial position-dependent representation. The local POE formulation of the kinematics and dynamics based on the theory of Lie groups and Lie algebras for rigid motion in $se(3)$ and $SO(3)$ can avoid this problem. Furthermore, the POE representation can avoid the singularity conditions that frequently occur in the kinematic calibration formulated by the DH method [22.20]. Thus, POE representations provide a uniform and well-behaved method for handling the inverse kinematics of both calibrated and un-calibrated robot systems. In local POE modeling, the joint axes are described in the local module (body) coordinate systems, it is progressive in constructing the kinematic models, so it conveniently resembles the assembling action of the physical modular robot components.

The machining tolerance, compliance, and wear of the connecting mechanism due to frequent module re-configuration may introduce errors in positioning the end effector. Hence, kinematic calibration is a must for modular robots. In the POE calibration model, the robot errors are assumed to be in the initial positions of the consecutive modules because the local POE model is a zero reference method. Based on linear superposition and differential transformation, a 6-parameter error model can be established for serial-type robots [22.19]. This model can be obtained through the automatic generation process. An iterative least-square algorithm employed to find the error parameters to be corrected. The corrected kinematic model is then updated in the robot controller for operation. The simulation and experiment have shown that the proposed method can improve the position accuracy up to two orders of magnitude, or to the nominal repeatability of the robot after calibration with measurement noise. A typical 6-DOF

articulate-type modular robot can reach a position accuracy of 0.1 mm compared to an accuracy of 1 mm before the calibration [22.20].

A formulation of the dynamic model of modular manipulators starts from a recursive Newton–Euler algorithm [22.21, 22]. The generalized velocity, acceleration, and forces can be expressed in terms of linear operations on $se(3)$ [22.23]. Based on the relationship between the recursive formulation and the closed-form Lagrangian formulation for serial-robot dynamics discussed in [22.24, 25], the AIM can assist in the construction of the closed-form equation of motion of a modular robot in any generic topology with redundant and non-redundant configurations [22.19].

22.2.5 Configuration Optimization

Due to the modular design, the modular manipulator can be optimal at the component level, but may not obtain optimal performance at the system level. Task-driven robot configuration optimization becomes necessary to establish locally optimal performance for the overall robotic system. Typically, the problem of robot configuration optimization can be stated as finding an assembly of robot modules that can achieve a certain task requirement based on an inventory of modules. The configuration of a modular robot can be treated as a compound entity with finite number of constituents. Finding the most suitable task-oriented robot configuration then becomes a discrete design optimization problem using a task performance related objective function. Discrete optimization techniques, such as genetic algorithms (GAs), the simulated annealing (SA) method, and other artificial intelligence techniques have been employed to find solutions [22.26–28].

The criteria used in selecting the optimal configuration depend largely on the task requirements, which mostly describe the necessary robot trajectories or key postures. Yang and Chen proposed a reduced DOF approach to minimize the total number of actuator modules employed in a serial-type modular robot for a given task [22.29]. With fewer modules, the robot can carry more payloads instead of carrying distal modules. Furthermore, the robot can be operated at higher speed with better dynamic response.

22.3 Self-Reconfigurable Modular Robots

Self-configurable systems can rearrange their own topology. An example is shown in  VIDEO 2. There are dozens of research groups who have constructed many versions of self-reconfigurable robots [22.3, 30–46], with many approaches for programming

them [22.36, 47–61]. As of 2012, over 800 papers and a book [22.31] have been written.

These systems are characterized by many identical modules that can be rearranged into a variety of shapes and configurations and by being highly scal-

able with simulated systems having hundreds, thousands, or millions of modules. These systems have three promises:

1. Low cost from batch fabrication of repeated modules
2. High robustness from redundancy and the ability to self-repair
3. High versatility from the ability to reconfigure and adapt to changing situations [22.62].

Practically speaking, none of the promises have been proven, though the promise of versatility is getting close. These systems have exhibited a wide variety of locomotion and manipulation including: legged walking with between 2 and 14 legs; riding a tricycle [22.63]; rolling like a tread [22.14]; snake-like locomotion (lateral and rectilinear undulation, concertina, sidewinding) [22.64]; manipulation of large objects with multiple arms/fingers [22.65]; manipulation of small objects; climbing stairs, fences, poles, in pipes; self-reconfiguration between dozens of shapes and many others [22.31]. Figure 22.4 and [VIDEO 1](#) show a self-reconfigurable modular robot SMORES [22.66]. Other self-reconfigurable robots like ATRON [22.40] is shown in [VIDEO 5](#) and M-blocks is shown in [VIDEO 3](#).

22.3.1 Types of Self-Reconfigurable Modular Robots

Self-reconfiguring systems can be classified into three types based on the style of reconfiguration: chain, lattice, and mobile [22.62]. The chain systems reconfigure by using chains of modules that form and break loops [22.36, 62]. They tend to be well suited for work on the environment, as they can form articulated limbs. The lattice systems have modules which have nominal positions sitting on a regular lattice and tend to be better at self-reconfiguration as moving to neighboring lattice positions makes collision checking easy [22.33, 34, 39, 43]. The mobile systems have modules that individually maneuver on terrain and reconfigure by moving on the environment to relocate themselves in a conglomerate [22.38, 67].

Of the systems that have been implemented to date, some that have been shown to be most capable (judging by number of demonstrations) are the hybrid chain-lattice systems: Superbot [22.14], MTRAN III [22.68] and CKbot [22.69]. Recent additions to this group are Johns Hopkins University [22.70], iMobot [22.71], and SMORES [22.66] which are hybrid in all three areas, chain-lattice-mobile systems.

22.3.2 System and Module Design Issues

There is an interesting phenomenon called second system syndrome [22.72], where designers include many features in the second version of a system they design. They often include many more features than the system may need. This is especially problematic in modular reconfigurable systems with repeated modules; any feature added to one module has the possibility of its effect multiplied by n , the number of modules. For example, an increase of d in computational processing power (e.g., microprocessor without interlocked pipeline stages, MIPS) in one module will result in a system increase of dn .

Another similar phenomenon for designers is called *feature creep*, where more and more features are added as the system is being designed. Often this has a cumulative linear effect on cost, but worse, there is an exponential effect on reliability.

The simplest form of robustness analysis assumes independent probabilities that a module may fail during a specified function. If one module succeeds during that function with probability p then the system with n identical module has a probability of success of p^n , under the assumption that all modules must be functioning to succeed. Clearly this is problematic for large n .

As systems scale up in number, a key to make things work is to be sure that the system does not depend on every module working perfectly. Indeed, if only X numbers are needed, one would wonder why one would use more than X , especially if the only impact is reduced reliability. Here, one strategy is to ensure that the solution is devised in a way where the performance improves with the number of modules. If modules fail, then the system can gracefully degrade. In systems with tightly coupled actions between modules, this can be difficult

Fig. 22.4 (a) One SMORES module with four main actuators and four docking faces. (b) Three SMORES modules attached together. (c) Two modules moving on a lattice

to implement. In tasks where only binary metrics exist, (success or failure) using the optimal X modules, setting aside the extras may be the best solution.

One of the aspects that researchers find most interesting about self-reconfigurable robots is examining what happens when modules scale up in number (and also typically, scaled down in size). As the numbers increase, the number of shapes/configurations increases and concomitantly, the types of activities that are possible increase as well.

Control and planning get very complicated quickly though. Simply enumerating the number of isomorphic configurations has resulted in a PhD thesis without completely solving the problem [22.15].

While researchers have simulated hundreds, thousands, and even millions of modules, no physical system has been demonstrated with more than a few hundred to date. The largest single system so far is Kilobot [22.73], which has very simple mobile modules that swarm together and actually do not connect rigidly. The modules communicate wirelessly in a one-to-many (broadcast) fashion. For rigidly connected systems the largest number of modules demonstrated in one connected system was a 14-legged 48-module Polybot system [22.74].

Main Actuation

Every module has some form of actuation that enables the modules to move from one position to another or to do some work on the environment. We call it the *main actuator*. By far the most common main actuator is a DC electric motor as it is the lowest cost and easiest to implement.

In chain systems, the main actuator typically drives a revolute joint so that a chain of modules forms an articulated arm. In lattice systems, the main actuator typically moves the module (or a neighboring module) along a constrained 1-DOF path that can be translation or rotation. In mobile reconfiguration, the main actuator enables locomotion, usually through wheels or treads.

The main actuator is typically the largest component in a module and so has been the focus when trying to make modules smaller. To date, the smallest module with onboard actuators, that both attaches and detaches uses shape memory actuated module that was 2 cm [22.75]. An even smaller 1 mm module was created at Carnegie Mellon University [22.76] using electrostatics as an actuator, but it did not attach to other modules.

On the other extreme, the largest module is GHC [22.77], an 8 m³ helium-filled cube with shape memory actuators on the edges to rotate these floating balloons about edges, attaching electrostatically. DARPA is also sponsoring a project to look at reconfigurable maritime craft constructed in a 20' ISO container

form factor. University of Pennsylvania has demonstrated scale models at 1/12 scale, with main actuators being thrusters to maneuver the parallelepipeds in water [22.78].

22.3.3 Interface Design Issues

The main component of modular systems differentiating it from an integrated system is the interface between modules. When talking about modular systems, the amount of *modularity* can be measured by the number of these interfaces. For self-reconfigurable modular robotic systems in this chapter the number of interfaces in one connected component can be as small as six or as large as millions.

In the most general case, every interface must do two things: 1) attach and 2) detach. When they attach they must do two things: 1) form a physical coupling and 2) allow a flow through the interface for supply power and information (often done electrically).

The interfaces can be *gendered* [22.36], that is two mating interfaces are not identical, one has male features sticking out and the other female features to receive the male features. They can be *ungendered* with no protruding or receding mating features. Or they can be *hermaphroditic* [22.39] where interfaces contain both male and female features. Ungendered and hermaphroditic interfaces can have identical interfaces on both sides. This increases the number of possible arrangements over gendered modules; however, ungendered and hermaphroditic components are typically more complex than gendered interfaces.

Each module can have multiple interfaces. If we consider the number of configurations possible with m interfaces per module assuming identical modules and ignoring any physical constraints such as self-collision, we obtain m^n possible configurations. The number of non-isomorphic configurations is much less, but is very difficult to enumerate in general. However, one special case to consider is two interfaces per module. In this case, topologically, there are only two different configurations, a single chain, and a loop. For this reason, most systems have three or more interfaces.

In addition, each interface can have multiple symmetries that allow different kinematic relationships for the same adjacency relationship. For example many systems have either a 2-way connector (modules may be optionally be rotated 180° to each other) or a 4-way connector (90° rotations.) This p -way symmetry leads to $(pm)^n$ total possible configurations.

Mechanical Interfaces

Mechanical interfaces rigidly attach two modules together with the ability to detach as well. Strategies to

enable this capability include using nuts and bolts, magnetic bonding [22.39], electrostatic bonding [22.77], probe and drogue [22.79], and a variety of physical hook-type mechanisms. Each mechanical interface has three performance metrics: bond strength, acceptance range, and interface precision/stiffness.

Bond strength can be characterized by the amount of force required to separate two modules in its weakest direction [22.80]. The acceptance range is the tolerance to position errors as two docks approach to dock [22.81]. Interface precision/stiffness indicates the amount of position error (deflection) that can occur contributed by the interface under load. This can come from elastic deflection, *slop* at a joint in a mate, or misalignments in non-self-guiding docks.

For self-reconfiguring systems, attaching and detaching is automatic and the area of acceptance is required to be much larger than typical manually assembled modular systems. This is in large part because the cost of precision is high and bond precision/stiffness is typically small. The ideal mechanical interface has high bond strength, high acceptance range and high bond stiffness, all of which comes with increased weight, size, and cost. However, different styles of reconfiguration emphasize different aspects.

Lattice reconfiguration systems do not need high acceptance range as modules move in highly constrained manner when reconfiguring, usually with one degree of freedom from one lattice position to neighboring one. However, high bond stiffness is emphasized, as these modules do not often have actuated degrees of freedom to compensate for errors in position. For example, a sequence of modules in a lattice that are forming a loop might not close properly because one section of modules may sag under gravity. This sag was noticeable in the 3-D lattice module [22.82].

Chain reconfiguration modules can deal with lower bond stiffness since they usually have degrees of freedom that can compensate for errors in deflection. However, docking even with this compensation is not trivial and most systems require as large an acceptance range as possible.

Bond strength for systems that reconfigure tend to be much lower than the one would find in a manually assembled system. For example, magnetic bonding methods are easy to implement, typically have good precision and wide range of acceptance, but are weak. Manual systems that are bolted together have high bond strength, but are very complicated if they are made automatic with a very small acceptance range. The variability in bond strength versus the stiffness in joints can be used to vary the overall stiffness of a conglomerate system [22.80]. This variable stiffness can be used to make a compliant material that can conform

to surfaces or a stiff material that will not bend under load.

Depending on the task, bond strength may not be required to be high. For example, in mobile reconfiguration systems that primarily move on the ground, e.g., forming trains such as *millibot* [22.67] or *swarms* [22.38], the worst case situation is when the conglomerate tries to cross a gap with modules cantilevered over the gap. Otherwise, the conglomerate is nominally supported at all times and the bond only sees dynamic friction and inertial forces. But in general, higher bond strength does not hurt and keeps a system from falling apart from static or dynamic loads.

Power and Communications Interface

Power and communications interfaces are typically electrical, though in the case of the related work in quick-change end effectors, pneumatics is often supplied too. In any case, the primary parameters of concern are the number of lines that must be transmitted between the interface, and the type of lines (e.g., pneumatic, high voltage, high current, fiber optic, etc.). The type of line will determine the size (which usually limits the number of lines) as well as the precision alignment required at the interface.

In self-reconfigurable systems, the typical interface passes electric power and a separate electronics communications bus on which all modules talk, though they are sometimes combined [22.77]. A key consideration for electronic lines is not only that the correct lines have good contact when mated, but also that wrong contacts do not touch during the docking process due to position error. For most self-reconfiguring systems maximizing the tolerance to position errors is the most important [22.56].

Communication between modules is essential for any self-reconfigurable system, whether the control is distributed or centralized. There are primarily two forms of communication: a global communications bus (any module talks to any other module) or a local communications medium (modules only talk to their neighbors through the modular interface.)

These two forms have different implications. Global buses are typically much faster than local methods of equivalent cost. There are no issues of varied latency between modules as with local methods. One problem with global buses is that there is no mechanism for modules communicating with each other to know the relative physical position of each module. Local methods get this for free. Local methods, can also emulate global architectures by message passing and routing. Local methods are also more robust to physical errors (such as shorting a communications line to power) containing failures to locally. However, they are just as

Table 22.1 Characteristics of used communication protocols

Method	Speed (kbs)	Range (m)	Power (mW)	Address space	Rel. cost	Notes
Ethernet/CAT	1k–1m	100's	500	≈4 billion	\$\$\$\$	Complex stack (IPV4)
CANbus	10–1000	100	≈ 200	≈ 2000	\$\$\$	Robust (base frame)
Bluetooth	1k–3k	10	≈ 100	≈1 million	\$\$\$	3 s wake-up
BLE (wibree)	1k	10	10	≈1 million	\$\$	Low power Bluetooth
Zigbee	20–250	10–75	≈ 30	64 bit	\$\$	Wakeup 15 ms
RS485	100–10 k	1200	5	256	\$	Robust elec. protoc
SPI	1–12 k	≈ 10	5	Out of band	\$	Simple sync 5 wire

vulnerable to software errors such as flooding a network with garbage messages.

There are many choices for global communication protocols falling into two categories: wired and wireless. Wired is the most common and has many possible protocols, mostly requiring that the bus is multidrop. Popular wired protocols include Ethernet, EtherCAT, RS-485, SPI, and CANbus. Popular wireless protocols include Zigbee, Bluetooth, and 802.11. Important characteristics of communication protocols include the speed, real-time aspects, address space, and cost. A comparison is shown in Table 22.1 with typical values of common implementation.

The importance of the speed depends (or often dictates) the architecture of distributed control. Communications to individual modules can range from 100 times

a second (for direct remote control) to several times per minute for higher level behavior control (e.g., hormone control [22.50]). Many protocols have automatic recovery from bad packets, which has obvious importance. Ethernet uses random backoff retransmission after a collision, which makes the protocol non-deterministic. This makes it difficult to have guarantees of real-time performance. The protocol is very fast so it is possible to ignore this as messages will get through with small latency with high probability. EtherCAT is Ethernet for Control Automation Technology that is better suited for real-time control. CANbus (Control Area Network bus) is a well-established bus used in the automotive technology that can be real-time, and robust, though it is typically slower than Ethernet or EtherCAT.

22.4 Conclusion and Further Reading

After more than a quarter century of research and development in modular robotics, a number of modular robotic systems have successfully entered the industry automation, education and entertainment markets. These successful modular robotic systems indicate that modular design offers advantages in the areas of product variety, application variety and creativity. However, the cost of such systems, no matter at the module level or at the system level, has room to be reduced to help mass adoption.

The cost structure of a modular robot is closely linked with the design of the individual modules and the systemic architecture to be conceived as well as the market demand and expectation. From the development history of LEGO bricks to the Schunk Powercube modules, it is clear that module design functions are becoming simpler (reducing cost) and increasing variability (increasing the user base). Hence, for reconfigurable modular manipulators, mobile systems, and self-reconfigurable modular robots, focusing on system designs to meet the expectation of the end user is the current trend.

Besides system design, standardization of mechanical and communication interfaces is critical. Like other electronic and industrial products, electronic and com-

munication interfaces for modular robots could adopt existing industry standards depending on the form factors, connecting performance, reliability, etc. The mechanical interface design normally does not have industry standard to follow due to variety in mechanical specifications on the form factor, loading capacity, rigidity of the joints. Hence, many novel mechanical connection designs can be explored for modular robots.

Future research continues to explore increasing the number of modules. As they approach hundreds and thousands, there are interesting questions that arise as modules become more tightly coupled than current efforts [22.73]. Issues include how to deal with the increased likelihood that some modular elements are not functioning completely correctly. Biologically inspired mechanisms such as intentional cell-death and cell-replacement may become a required part of very large systems.

As the modular approach has increasingly large numbers of modules, there are many more configurations and resulting capabilities from those configurations. Future research will need to address the problem of determining appropriate or optimal configurations

for arbitrary tasks. This may lead to a better understanding of robotic tasks in general.

The most recent review article on modular mobile robots can be found in [22.13]. In [22.30], the

technical challenges and future of self-reconfigurable modular robots are reviewed. Interested readers may find further information on self-reconfigurable robots in [22.31].

Kyu-Jin Cho, Robert Wood

Biomimetic robot designs attempt to translate biological principles into engineered systems, replacing more classical engineering solutions in order to achieve a function observed in the natural system. This chapter will focus on mechanism design for bio-inspired robots that replicate key principles from nature with novel engineering solutions. The challenges of biomimetic design include developing a deep understanding of the relevant natural system and translating this understanding into engineering design rules. This often entails the development of novel fabrication and actuation to realize the biomimetic design.

This chapter consists of four sections. In Sect. 23.1, we will define what biomimetic design entails, and contrast biomimetic robots with bio-inspired robots. In Sect. 23.2, we will discuss the fundamental components for developing a biomimetic robot. In Sect. 23.3, we will review detailed biomimetic designs that have been developed for canonical robot locomotion behaviors including flapping-wing flight, jumping, crawling, wall climbing, and swimming. In Sect. 23.4, we will discuss the enabling technologies for

these biomimetic designs including material and fabrication.

Biomimetics is a broad field that covers all ranges of robotics including robot structure and mechanics, actuation, perception, and autonomy. This section will focus on robots that mimic structure and movement principles found in nature to perform desired tasks in unstructured environments.

Nature frequently inspires engineers to adopt solutions from biology for application to human challenges. Robots are built to perform certain tasks, and many tasks include moving from one place to another. The various

modes of locomotion in nature have inspired robots to mimic these locomotion with a goal to overcome various obstacles in the environment, and move around with the extreme agility similar to that found in nature. Mankind has engineered various modes of transportation on ground, air, and water. On ground, wheeled vehicles are the most popular choice. In air, fixed wing airplanes and helicopters with rotating blades dominate, and in water, ships, and submarines propelled by similar rotating elements are most common. In contrast, nature

has different solutions to locomotion involving moving legs, undulating fins, and flapping wings. Many of these biological locomotion mechanisms have analogies to engineered systems. Instead of using wheels, nature uses legs of different sizes, numbers, and impedances; humans and birds are bipedal, many mammals and reptiles move on four legs, and insects have six legs, and other arthropods have eight or more legs. These legs are coordinated to move on different surfaces in a stable manner. Snakes and worms move around without legs

by creating waves with their body. Instead of fixed wings with jets and rotary propellers, birds, bats, and flying insects flap their wings. Fish create undulatory motions with their bodies to swim with agility far beyond conventional boats and submarines. Each of these biological locomotion modes are based on the nature's fundamental actuator: muscle. Muscles create linear motion that is coupled to the structures that generate locomotion. Therefore, these structures are closely related to the morphology of the muscles that move the structures.

23.1 Overview

The main purpose of locomotion in manmade machines is to deliver large payloads across long distances in the shortest possible time or with the minimal energy expenditure. There are roads, airports, shipyards, and other foundations that support this transportation, enabling the structural design of cars, trains, planes, and ships to focus on transportation tasks. On the other hand, locomotion in nature is primarily for survival. Animals and insects have evolved to survive in various environments. Each species uses their mode of locomotion to hunt for food, find mates, and escape danger all in unstructured natural environments. Therefore, the requirements for biological locomotion are much more complicated than human transportation systems.

Biomimetic robots try to mimic the structural characteristics and the principles of movement to be able to move around places where conventional machines or robots are unable to perform as needed. Animals can crawl on a rugged terrain at a high speed, can climb walls without a tether, can fly in cluttered environments and hover and perch as needed.

Depending on the size of the species the optimal mode of locomotion and the underlying structure is different. For example, jumping is found frequently in small insects to escape danger, since their small size makes it hard for them to escape quickly using other forms of locomotion. Jumping by a large animal is different from jumping by small insects like a flea. Larger insects or animals tend to use their legs to run or crawl to escape the danger. Large birds flap their wings at a much lower frequency, and use gliding mode whereas bees and flies beat their wings continuously at a high frequency during flight. The structure is very differ-

ent, where the wings of a bird have bones, muscle, and feathers versus the muscle-less and lightweight wings of insects. Therefore, when developing biomimetic robots, the size of the target species should be taken into account.

Since nature has evolved to survive in extreme environments, there are many examples of extreme locomotion that are typically not possible with conventional engineering designs. For example, the wall climbing robot Stickybot uses the directional adhesion principle of a gecko to climb up smooth vertical walls. However, directional adhesion alone is not enough. The design has to enable even pressure distribution on the pad to make sure the pads are well in contact with the wall. These small details can be important to performance of biomimetic robots and should be considered carefully.

Since robots are commonly built to perform tasks too tedious or dangerous for humans, it is natural to adopt designs found in nature for functionality where nature has already found a solution. In fact, many robot designs in this handbook, such as legged robots and robot hands and many examples of flying robots, underwater robots, and micro robots, are biomimetic. This chapter will focus on areas of biomimetic robot designs that have been recently expanding. Legged robots and robot hands have already formed large communities and are covered in separate chapters. There are various other forms of locomotion, e.g., crawling, jumping, swimming, and flapping, that are being researched to mimic the principle of movement and the biological structure. The structure and the components of these robots will be reviewed and discussed in this chapter.

23.2 Components of Biomimetic Robot Design

Biomimetic robot design begins with an understanding of the underlying principles at work in a natural system.

For the design of a biomimetic robot, the components used in building the robot are important; the structural

design is constrained or enabled by the actuator system, the materials and the fabrication methods used to build the robot.

Understanding of the principles of movement found in nature initiates the design of biomimetic robots. This can be studied by observing the kinematics and measuring forces in moving animals, or by understanding and modeling the dynamics. Substantial research on biological locomotion analyzes the kinematics of the animal. However, it is important to understand the dynamics behind the kinematics to be able to implement the dynamic principles into the robot design, which will enable the robot to perform like an animal, instead of just looking like one. *Full* et al. proposed clock-driven, mechanically self-stabilizing, compliant sprawled-posture mechanics to explain a cockroach racing seemingly effortlessly over a rough surface [23.1, 2]. *Ellington* built a system that can measure the force generated by flapping wings to understand the thrust generated by insect wings [23.3]. These studies in biology have influenced robotics researchers, and inspired them to build hexapod and flapping-wing robots.

To implement biological principles in engineered systems, components that can create performance similar to that of nature is required. Nature's biological structures are composed of various materials, e.g., tissues, bones, cuticles, flesh, and feathers. These materials are replaced with engineered materials, e.g., metal, plastics, composites, and polymers. New engineered materials are being developed that exhibit similar properties to natural materials, which will enable life-like robots. However, the performance of the biomimetic robot can be similar to nature without actually mimicking the exact structure. Therefore, it is important to decide to what level biomimicry is re-

quired. Large robots tend to be built with conventional mechanical components such as motors, joints, and linkages made of metal. The challenge is in building meso-scale robots, where the conventional mechanical components become ineffective, due to friction and other inefficiencies. As the robot becomes smaller, it is beneficial to mimic not just the kinematics seen in nature, but also the structure at the component level. Another challenge for small scales is actuation – the actuator must be as effective as the muscle even at small scales.

A number of new manufacturing methods have become available which also enable new designs that were not previously possible by more classical machining methods and *nuts-and-bolts* assembly techniques. Examples include shape deposition manufacturing and smart composite microstructures. In many cases, these new fabrication processes facilitate the construction of novel biomimetic robots beyond what was possible by conventional means.

Levels of mimicry can vary depending on the components used in the design. The robot can simply look like an animal, but not perform similarly to the mimicked animal. On the other hand, once the principle is mimicked the robot does not have to look like the animal, but it can still perform a task in a similar manner as the animal. The different ways of mimicking allows each robot to have its own characteristic. For example, a flea uses what is called a torque reversal for jumping, which is a unique method of storing and releasing large amount of energy. In nature, this method is possible with muscles and a lightweight-legged structure. To mimic the flea's locomotion, we need an actuator that is comparable to muscles and a fabrication method that allows us to build a small-scale rigid structure.

23.3 Mechanisms

Developing multilegged robot has been achieved by using specific design which enables some function or biomimetic model inspired by multilegged insects. Especially, the ability of a cockroach enabling to run on a rough surface at a high speed has inspired to develop a series of multilegged robots. They are capable of maintaining stability during locomotion at a high speed (relative to their body length).

23.3.1 Legged Crawling

Some types of cockroaches can achieve speed up to 50 body length per second and can crawl on uneven terrain, overcoming obstacles far higher than their height [23.2]. RHex (Fig 23.1a) [23.4] is one of the

first robots to implement cockroach-like characteristics. It is a hexapod crawling robot with C-shaped legs, so it is suitable for walking on uneven terrain or large obstacles, as shown in  VIDEO 400. Mini-Whigs (Fig 23.1b) [23.5] also have unusual wheel with three spokes. Because of the wheel-spoke structure, the gait passively adapts to the terrain similar to climbing cockroaches, as shown in  VIDEO 401 [23.15]. Sprawlita (Fig 23.1c) [23.6] is a hexapod crawling robot that uses pneumatic actuators on each leg and passive rotary joints so that it can achieve dynamic stability. It weighs 27 kg and its speed is over 3 body length/s or 550 mm/s. iSprawl (Fig 23.1d) [23.7] is hexapod crawling robot that uses extension of each legs during crawling. This robot is driven by electric motors and

Fig.23.1a–d Crawling robots inspired by cockroach (a) RHex (after [23.4]), (b) Mini-Whegs (after [23.5]), (c) Sprawlita (after [23.6]), (d) iSprawl (after [23.7])

Fig.23.2a–g Crawling robots inspired by cockroach. (a) DASH (after [23.8]), (b) RoACH (after [23.9]), (c) DynaRoACH (after [23.10]), (d) OctoRoACH (after [23.11]), (e) HAMR3 (after [23.12]), (f) centipede-like modular robot (after [23.13]), (g) crawling robot through the integration of microrobot technologies (after [23.14])

flexible push–pull cables. Rotation of the motor causes the legs to extend or contract. It weighs 300 g and is able to crawl 15 body length/s or 2.3 m/s, as can be seen in [VIDEO 403](#).

Cockroach-based designs would improve the performance of millimeter or centimeter scale crawling robots which face inefficiency with conventional mechanisms. DASH (Fig 23.2a) [23.8] is a hexapedal crawling robot fabricated using SCM (Smart composite manufacturing) process. This robot has only one electric motor coupled to a four-bar linkage pushing the legs in an elliptical crawling motion, as shown in [VIDEO 405](#). DASH weighs 16.2 g and achieves

speed up to 15 body length/s or 1.5 m/s. RoACH (Fig 23.2b) [23.9] is a hexapod crawling robot that imitate cockroach's alternating tripod gait. A typical cockroach gait involves the ipsilateral front leg, hind leg, and contralateral middle leg moving simultaneously. Two sets of three legs tread on a surface in turn – generating the *alternating tripod gait*. RoACH uses two shape memory alloy (SMA) wire actuators to contract the body in two orthogonal directions. Contraction of the two actuators results in motion of legs through a four-bar linkage. The legs repeatedly operate swing and stance motions according to the sequential stimulation of the two actuators and it can be seen in [VIDEO 286](#). It weighs 2.4 g and is able to crawl 1 body length/s or 3 cm/s. DynaRoACH (Fig 23.2c) [23.10] has six legs driven by one DC motor. It has passive dynamics similar to RoACH to achieve better locomotion performance. Lift motion is achieved by a slider crank mechanism and swing motion by a four-bar mechanism. Like RHex, it uses C-shape legs so that the robot has lower vertical stiffness, lateral collapsibility for obstacle climbing, and more distributed ground contact. It weigh 24 g and is 100 mm long and is capable of speeds up to 14 body length/s or 1.4 m/s. OctoRoACH (Fig 23.2d) [23.11] is quite similar to DynaRoACH, but it has two motors driv-

Fig.23.3a,b The latest version of crawling robots which shows improved performance (a) HAMRV (after [23.16]), (b) VelociRoACH (after [23.17])

ing the legs on each side. It has eight legs so that it maximizes pitch stability using two motors. OctoRoACH weigh 35 g and is 100 mm long. HAMR3 (Fig. 23.2e) [23.12] uses nine piezoelectric actuators. Each leg performs swing and lift motion through two decoupled piezoelectric actuator through four-bar slider-crank mechanisms and spherical five-bar mechanisms (👁️ VIDEO 406). This robot weighs 1.7 g and has speeds up to 0.9 body length/s or 4.2 cm/s (4.7 cm long robot). Especially, the HAMR is manufactured using a method inspired by pop-up books that enables fast and repeatable assembly. Multilegged robots inspired by centipede using mechanism similar to alternative tripod gaits is also developed (Fig. 23.2f) [23.13]. Its several gait patterns that differ in gait frequency and phase are described in 👁️ VIDEO 407. Using microrobot technologies developed until 2006, integrated structure was developed although the structure was not yet tested (Fig. 23.2g) [23.14].

With more experiments and research about motion of cockroaches, the cockroaches like robots can extremely improve their performance by revision using biomimetic model. HAMRV, which is the most recent version of HAMR [23.16], can move 10.1 body length/s (44.2 cm/s) which is remarkably improved compared to preceded versions are capable of running at 0.9 body length/s. It is even capable of maneuverability and control at both low and high speeds. VelociRoACH (Fig. 23.3b) [23.17] which is the latest version of RoACH can run 2.7 m/s extremely higher speed relative to previous version (👁️ VIDEO 408).

23.3.2 Worm-Like Crawling

Worm-like crawling motion can be separated into two categories: peristaltic crawling and two-anchor crawling. Worms exhibiting peristaltic crawling locomotion – such as earth worms – can move through small tunnels with limited space. Therefore, mimicry of this locomotion imposes similar characteristics to the robot and it has the potential to be used in small and harsh environment such as collapsed disaster site or inside a pipe line. which A schematic of peristaltic locomotion is shown in Fig. 23.4. By sequentially changing the volume of the body, the whole structure generates the moving motion.

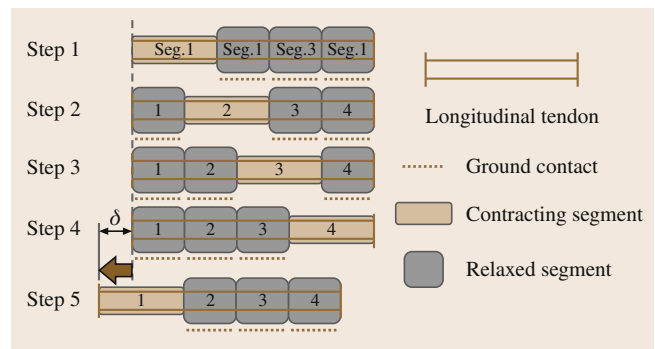

Fig. 23.4 Peristaltic locomotion (after [23.19])

The key design issue in mimicking peristaltic motion is how to create sequential volume change. Many researchers have tried various creative methods to solve this problem. *Boxerbaum* et al. built a robot with a mesh structure, and using a single motor and wire, made a partial volume change of the robot which realized a crawling motion (Fig. 23.5a) [23.18]. *Seok* et al. used a SMA coil spring actuator to change the segmented volume, and also used a mesh tube as the body structure (Fig. 23.5b) [23.19]. *Menciassi* et al. also used a SMA coil spring actuator, but they used a micro hook to enhance the friction force (Fig. 23.5c) [23.20].

Two-anchor crawling is a locomotion method used by inchworms. This locomotion mode is not fast, but it can overcome nearly any complicated topology. With an appropriate gripping method, it not only can climb vertical walls, but also can cross gaps. There are two key design issues for generating a two-anchor crawling motion: the first is how to change the shape of the waist and the second is how to anchor and unanchor to the surface. *Kotay* and *Rus* simply used an electric motor to articulate the waist motion and used an electromagnetic pad as the anchoring method (Fig. 23.6a) [23.21]. Using an electromagnetic pad, the robot can climb a steel structure. *Cheng* et al. used a tendon-driven mechanism with a compressible body and an anisotropic friction pad to generate motion (Fig. 23.6b) [23.22]. Using symmetrical or asymmetrical winding of the wire attached on the both side, the robot can make forward or steering movements. *Koh* and *Cho* used SMA coil spring actuators to control the waist motion (Fig. 23.6d) [23.23].

Fig. 23.5 (a) Robot with peristaltic motion (after [23.18]). (b) Meshworm robot (after [23.19]). (c) Biomimetic miniature robotic crawler (after [23.20])

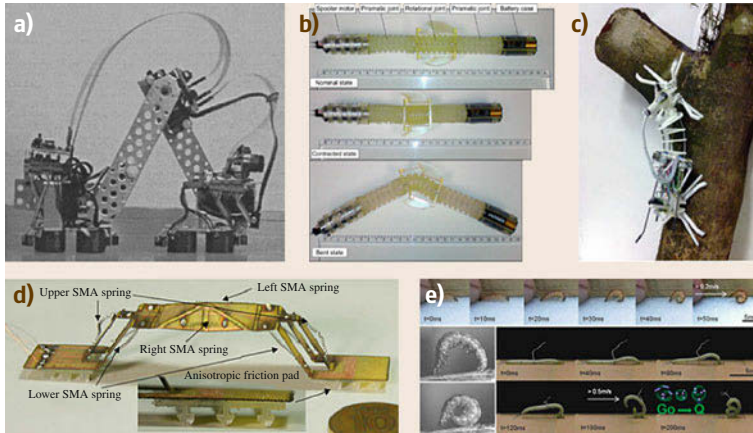

Fig.23.6a–e Two anchor crawling robot. (a) The inchworm robot (after [23.21]). (b) The soft mobile robot with thermally activated joint (after [23.22]). (c) Treebot (after [23.24]). (d) Omega shaped inchworm inspired crawling robot (after [23.23]) (e) GoQBot (after [23.25])

The body of the robot is made by a single sheet design with glass fiber composite, and a folding pattern designed to enable steering motion even though the robot was built by a single sheet. *Lin et al.* realized a robot with two-anchoring motion, but he also added a rolling locomotion to solve the speed limitation of previous two-anchor motion demonstrations (Fig. 23.6e) [23.25]. *Lam and Xu* realized another method to generate the waist motion. The robot used a backbone rod coupled to an electrical motor. By controlling the length of the backbone using the motor, the robot can control the position of the anchoring point (Fig. 23.6c) [23.24].

23.3.3 Snake Robots

Studies on the locomotion of snakes began in middle of the 20th century [23.30–32]. Snakes are limbless, slender, and flexible [23.33]. Their locomotion gives them adaptability and mobility through land, uneven ground, narrow channel, pipes, and even water, and even flying between trees [23.34, 35]. An advantage of snake-like locomotion is the great versatility and freedom of movement with numerous degrees of freedom [23.36]. Additionally, snake locomotion could be efficient compared to legged animals, because there is no lifting of the center of gravity or limb acceleration [23.37]. In 1970s, *Hirose* developed a continuous locomotion model and a snake-like robot called the *Active Cord Mechanism (ACM)* [23.38]. After the *Hirose's ACM* robot, snake-like robots have been widely studied. In 1972, *ACM-III* (Fig. 23.6) was developed and it was the first robot that mimics the serpentine motion of real snakes [23.38]. The recent versions of *ACM* are in [VIDEO 397](#).

Locomotion of snake-like robots can be categorized into the following different types: serpentine motion, sinus lifting, pedal wave, side-winding, spiral swimming, lateral rolling, lateral walking, mixture lean serpentine, and lift rolling motions.

The first generation of snake-like robots could only achieve motion on planar surfaces. These designs quickly evolved and current snake-like robots can go upward within narrow pipes and can climb and hold on to trees like [VIDEO 393](#) [23.39]. To facilitate traversing large obstacles, some robots have added actuated articulation between each joint [23.40]. In addition, there are some snake-like robots that can swim in water. With a firmly waterproofed body, these robots can swim with spiral and sinusoidal locomotion patterns [23.38].

Today, mechanism design of snake-like robots can be classified with following five different types: active

Fig.23.7a–d Three snake-like robots. (a) AMC-III, Shigeo Hirose, Fukushima Robotics Lab, Tokyo Institute of Technology (after [23.26]), (b) Slim Slime Robot II (SSR-2), Shigeo Hirose, Fukushima Robotics Lab, Tokyo Institute of Technology (after [23.27]), (c) Modular snake robot, Howie Choset, Biorobotics Lab, Carnegie Mellon University (after [23.28]), (d) AMC-R5, Shigeo Hirose, Fukushima Robotics Lab, Tokyo Institute of Technology (after [23.29])

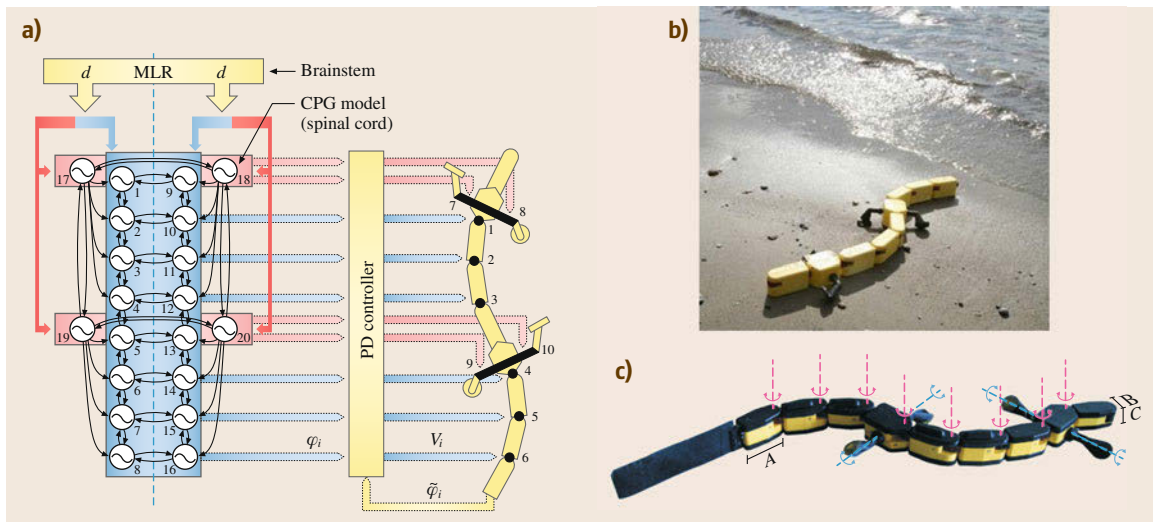

Fig. 23.8 (a) Configuration of the CPG model (after [23.41]). (b) Salamandra robotica I, Auke Jan Ijspeert, Biorobotics Lab, Ecole Polytechnique Federale de Lausanne (after [23.41]). (c) Salamandra robotica II, Auke Jan Ijspeert, Biorobotics Lab, Ecole Polytechnique Federale de Lausanne (after [23.42])

bending joint type, active bending and elongation joint type, active bending joint and active wheel type, passive bending joint and active wheel type, and active bending joint, and active crawler type [23.43]. Each of these types of snake-like robots consist of a number of serially connected joints. Therefore, snake-like robots are easy to modularize with their joints [23.43].

Most snake-like robots are equipped wheels that are actively or passively driven. Recently, wheelless snake-like robots have been studied [23.32]. These robots move with undulatory motion, especially lateral undulation that can be observed in real snakes. Some snake-like robots are actuated with smart materials, such as shape memory alloys and IPMCs, rather than motors [23.44]. Snake-like robots roll to avoid obstacles and interact with environment. They make waveforms with their body for propulsion. Therefore, it is important to define the configuration of the body of the robots. Measuring yaw (pitch) and roll angles are important for controlling the snake robots. Tilt sensors, accelerometers, gyroscope, and joint angle sensors are typically leveraged to control the robot [23.37]. Tactile sensors attached to the contact area or outside of the body of the snake-like robots have been used to measure surface contact forces at each joint, providing more information to the controller. Additionally, measuring contact forces could be useful for active and adaptive grasping of the snake-like robot [23.45].

However, due to the high degrees of freedom of the snake-like robots, designing controllers is not easy even for flat surface locomotion. Efforts without complex sensors and controllers are in [VIDEO 392](#). Because of

this, contrasting with the advantages of locomotion of real snakes – which can move in uneven environments – most existing snake-like robots are developed based on flat surface movement [23.46].

A major motivating application for snake-like robots is the exploration of hazardous environment that are inaccessible to humans. In particular, industrial inspection of pipes and ventilation tubes, and chemical channels are key operating environments. There is also the potential for snake-like robots as medical devices, such as minimal invasive surgery device and laparoscopy and endoscopy [23.37]. For these applications, snake-like robots require their outer skin to hermetically seal the internal components [23.40].

There are numerous challenges for snake-like robots. For greater reliability, robustness and controllability, the mechanisms and configuration of the snake-like robots could be simplified. To use the snake-like robots for exploration and inspection applications, routing of external wires for electronics and power to the robot is an important consideration. Finally, with a large number of degrees of freedom typical of snake-like robots, designing efficient control strategy is large issue [23.37].

Similar to undulatory locomotion of snakes, body of salamanders makes S-shape standing waves. They are capable of rapidly switching between swimming and walking locomotion. Their locomotion in aquatic and terrestrial environments is generated by a central pattern generation (CPG) and stimulation of a mesencephalic locomotor region (MLR) located in the mid-brain (Fig. 23.7 and [VIDEO 395](#)) [23.41]. There were

some efforts to produce similar swimming and walking gaits to real salamander with robotic salamanders. The salamander robots with the mathematical CPG model, DC motors, and oscillators could produce similar kinematics to real salamanders [23.42] (Fig. 23.8).

23.3.4 Flapping-Wing Flight

Flapping-wing flight is a common inspiration for biomimetic aerial robots. This is due to the agility of natural flyers such as birds, bats, and insects. Advances in the understanding of the aerodynamics of flapping-wing based on hydrodynamic theories and experimental results have provided insights into thrust production in flapping-wing animals [23.47]. From observation of the flapping motion exhibited by insect flight, the translational, and rotational motions of the wing produce lift forces at high angles of attack – beyond what is typical for fixed wing aircraft. The formation of a large vortex at the leading edge of the wing and the recapturing of shed vortices by properly timing of the swing enhance the resultant lift force [23.48]. Figure 23.9 shows the representative motion of an insect wing during flight and the vector formation of hydrodynamic forces. Such characteristics learned from nature inspires the design of wing-driving systems in flapping-wing flying robots.

Most flapping mechanisms are constructed from electromagnetic rotary motors driving crank-rocker linkages to flap the wings. Examples include the DelFly II [23.49], Robot dragonfly [23.50] and Nano Hummingbird [23.51] as shown in Fig. 23.10. As can be seen in [VIDEO 402](#), DelFly II employs four-wing morphology where two wings on each side perform

a *clapping* motion during each period. This contributes to lower power consumption and the low rocking amplitude of the fuselage. The DelFly II model used a crank mechanism such that the gear axis is perpendicular to the flying direction, for overcoming phase differences between the two sets of wings and this difference induced rotational movement on the fuselage [23.49]. In related work, the Robot Dragonfly [23.50] is inspired from a dragonfly's hovering capabilities and utilizes a tandem wing model. Each transmission link is attached to gear mechanisms that can make wing motions similar to those of a dragonfly. The Nano Hummingbird uses single pair of flapping wings as with real hummingbirds. The flapping mechanism is a dual lever, string-based flapping mechanism. Wing rotation modulation for control of the wing attack angle is achieved by the two adjustable stops which limit how far each wing can rotate [23.51]. Alternative mechanisms use oscillating actuators and flexure-based transmissions systems (these mechanisms are discussed in Sect. 23.4.2).

As the robot scale decreases, previous flapping mechanisms have been difficult to adapt due to manufacturing challenges and the physics of scaling. The Harvard robotic fly shows promising fabrication and design processes to build the small scale flapping air vehicle as shown in Fig. 23.11 [23.52]. Previous versions of the Harvard robotic fly had three degrees of freedom, only one of which was actuated. The angle of attach of two the wings are passively controlled by a compliant flexure joint connected to the transmission. The wing beat frequency is tuned at 110Hz in resonance. Through advances in meso-scale manufacturing methods, the capabilities of the robotic fly have been dramatically extended and unconstrained flight

Fig. 23.9 Diagram of wing motion indicating magnitude and orientation of the aerodynamic force (after [23.48])

Fig. 23.10 (a) Delfly II (after [23.49]), (b) Robot Dragonfly [23.50], (c) Nano Hummingbird (after [23.51])

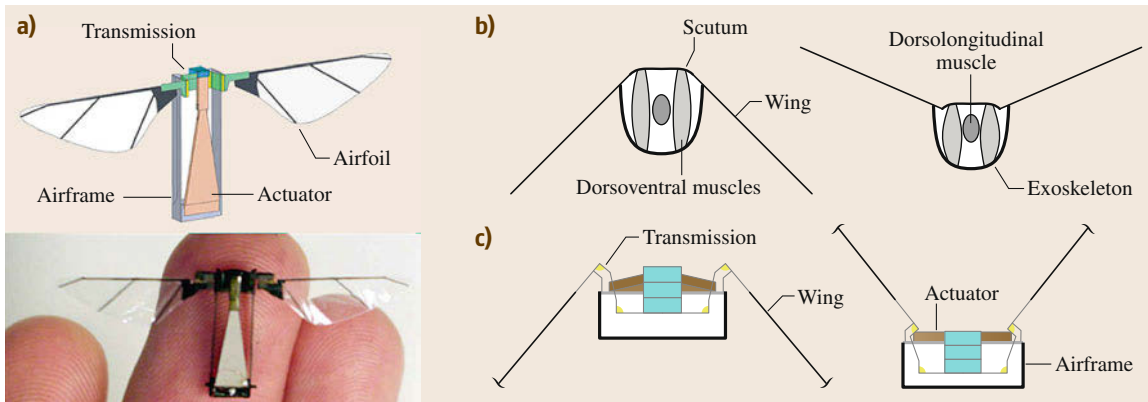

Fig. 23.11 (a) Harvard robotic fly, (b) Illustrations of thorax mechanisms, (c) and transmission (after [23.52])

has been demonstrated like  VIDEO 399 in an 80 mg robot as discussed in Sect. 23.4.2.

Flapping-wing locomotion can also be extended to multimodal locomotion in combination with other mechanisms. In the DASH+Wings shown in Fig. 23.12 [23.53], the combination of wing flapping and crawling compliments each other for improving agility and stability. This hybrid robot improves performance of the maximum horizontal running speed in a factor of two and the maximum climbing incline angle by a factor of three.

23.3.5 Wall Climbing

Climbing and maneuvering on vertical surfaces present a difficult challenge. However, this locomotion mode is needed in many areas such as shipping, construction, and terrestrial locomotion in natural environment. Early attempts involved the use of suction cups, magnets,

Fig. 23.12 DASH+Wings (after [23.53])

or pressure-sensitive adhesives to implement climbing. More recently, claw, spines and sticky pads inspired by nature have been used. Climbing insects and animals inspired many researchers. Insects and reptiles employ small spines that catch on fine asperities. Geckos and some spiders employ large numbers of very fine hairs that achieve adhesion based on van der Waals interaction.

Early in the 1990s, nonbiomimetic wall climbing robots, i.e., the Ninja-1, RAMR, and Alicia were developed using suction cup. Ninja-1 attaches to a wall making use of a suction mechanism (Fig. 23.13a). The main mechanism consists of a three-dimensional (3-D) parallel link, a conduit-wire-driven parallelogram, and valve-regulated multiple sucker that enabled the robot to attach the surface with grooves [23.54]. RAMR used underactuation to remove the redundant actuators to drive the small two-legged robot [23.59]. The Alicia robot was developed for a variety of applications such as maintenance, building inspection, and safety in process and construction industries. An aspirator is used to depressurize a suction cup, so the whole robot can adhere to the wall like a standard suction cup. The Alicia3 robot use three of the Alicia II modules, allowing the whole system to better deal with obstacles on the target surface [23.60]. REST is an exceptional case that applies electromagnets instead of suction cup. It climbed only ferromagnetic wall using electromagnetic four legs with 12-DOF [23.61].

The effective wall climbing mechanisms of animals and insects have inspired development of biomimetic wall climbing robots. Typical robots utilizing bio-inspired spines found in climbing insects and cockroach are Spinybot and RiSE. Spinybot in  VIDEO 388 climbs hard vertical surfaces including concrete, brick, stucco, and masonry with compliant microspine arrays (Fig. 23.13b). It can exploit small asperities (bumps or pits) on the surface. The sequence of motions is

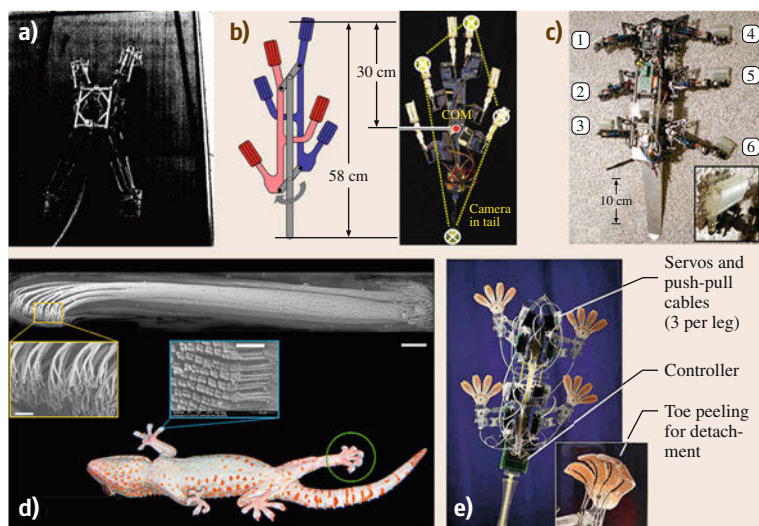

Fig. 23.13 (a) Ninja-1 (after [23.54]), (b) Spinybot II (after [23.55]), (c) RiSE (after [23.56]), (d) Gecko adhesive system (after [23.57]), (e) Stickybot (after [23.58])

accomplished using an under-actuated mechanism consisting of a single rotary RC servo motor and several spines independently engaging asperities on the concrete surface [23.55]. RiSE is a hexapod robot capable of locomotion on ground and vertical surfaces such as brick, stucco, crushed stone, and wood, as shown in [VIDEO 390](#) (Fig. 23.13c) [23.56]. To climb a vertical wall, it uses microspines inspired by cockroach's tarsus structure. In addition, it held its center of mass close to surface to minimize the pitch-back moment. RiSE also employed a static tail to reduce disparity from the pull-in forces experienced by the different legs [23.56, 62].

Insects and geckos can provide inspiration for novel adhesive technology and for the locomotion mechanisms employed during climbing. Geckos are able to climb rapidly up smooth vertical surfaces and biologists reveal that a gecko's foot has nearly five hundred thousand keratinous hairs or setae. And measured adhesive force values show that individual seta operate by van der Waals forces. The gecko's toe uncurling and peeling suggests that two aspects of setal function increase effectiveness [23.63]. The subsequent study shows that the linear relation between adhesion and shear force is consistent with a critical angle of release in live gecko toes and isolated setal arrays (Fig. 23.13d). And the frictional adhesion model provides an explanation for the very low detachment forces observed in climbing geckos that does not depend on toe peeling [23.57].

Stickybot, Mini-Whegs, Geckobot, and Waalbot are prototypical robots that leverage biomimetic dry adhesives. Stickybot climbs smooth vertical surfaces such as glass, plastic, and ceramic tile at 4 cm/s, as shown in [VIDEO 389](#) (Fig. 23.13e). The robot employs several design principles adapted from the gecko including a hierarchy of compliant structures, directional adhe-

sion. The undersides of Stickybot's toes are covered with arrays of small, angled polymer stalks. They readily adhere when pulled tangentially from the tips of the toes toward the ankles. When pulled in the opposite direction, they release [23.58]. Mini-Whegs uses wheel-legs with compliant, adhesive feet for climbing. The foot motion mimics the foot kinematics of insects, in order to test new bio-inspired adhesive technologies and novel, reusable insect-inspired polymer (polyvinylsiloxane) [23.67]. Geckobot has kinematics similar to a gecko's climbing gait. It uses a novel peeling mechanism of the elastomer adhesive pads, steering mechanisms and an active tail for robust and agile climbing [23.68, 69]. Waalbot used two actuated legs with rotary motion and two passive revolute joints at each foot. The robot has ability to climb on nonsmooth surfaces as well as on inverted smooth surfaces using gecko-like fibrillar adhesives and passive peeling. It is also capable of plane-to-plane transitions and steering to avoid obstacles [23.70].

Different approaches for climbing include electroadhesion. Electroadhesives use a novel clamping technology called compliant electroadhesion – a form of electrically controllable adhesion. This involves inducing electrostatic charges on a wall substrate using a power supply connected to compliant pads situated on the moving robot. This generates high clamping forces that are around 0.2–1.4 N supported for a one square centimeter clamp area, depending on the substrate. Regarding power considerations for electroadhesion, assuming 50% conversion efficiency, in the worst-case scenario, two AAA batteries weighing 7.6 g each can hold up a robot in *perch* mode for almost one year. Electroadhesion combined with a conventional wheeled robot results in inchworm-style wall climbing [23.79].

Fig. 23.14 (a) DynoClimber (after [23.64]). (b) A dynamic template for climbing (after [23.65]). (c) CLASH with gecko pad (after [23.66])

Dynamic wall climbing is the next challenge for wall climbing robots because previous robots were slow and in most instances restricted to targeted surfaces. For dynamical climbing originating in biology, pendulous climbing model was proposed (Fig. 23.14b). This model abstracts remarkable similarities in dynamic wall scaling behaviour exhibited by radically different animal species such as cockroaches and geckos [23.65]. The findings suggest that animals employ large lateral in-pulling forces and body rotations to achieve fast, self-stabilizing gaits. DynoClimber displays the feasibility of adapting the dynamics to robot that runs vertically upward (Fig. 23.14a). A novel bi-pedal dynamic climber can scale a vertical wall fast accompanying while achieving dynamic stability. For dynamic climbing, this robot consists of a DC motor, a crank slider mechanism and passive-wrist springs so its climbing at speeds 0.67 m/s (1.5 body lengths/s) [23.64]. The climbing robot CLASH has modified DASH platform but it actuates in horizontal direction to reduce height (7 mm from robot bottom). One of the key points is passive foot mechanism. When climbing upward, the foot hangs its spines on the surface and then retracts passively. This increases the shear and normal forces and enables climbing on loose cloth at 15 cm/s speed, as shown in [VIDEO 391](#) [23.80]. The next version of CLASH has a foot that consists of an 18×15 mm pad of microfabricated PDMS (polydimethylsiloxane) ridges inspired by gecko feet (Fig. 23.14c). The ankle is an isosceles-trapezoid four-bar that creates a remote center-of-motion. This mechanism allows the foot to make coplanar contact with the surface and reduces roll peeling moments [23.66].

23.3.6 Swimming

Underwater vehicles have been made to achieve marine explorations, surveillance, and environmental monitoring. Most underwater vehicles employ propellers for

propulsion and these vehicles have shown great performance with respect to the cost of transport. However, efficiency and manoeuvrability in confined areas is problematic for most surface or underwater vehicles. Moreover, propeller-driven vehicles risk tangling when moving through environments with debris and vegetation. To resolve these issues, researchers have tried to replace the conventional rotary propellers with undulatory movement inspired by fish (Fig. 23.15).

The undulatory movement of fish provides two main advantages – manoeuvrability in confined areas and high propulsive efficiency. The main difference between existing propeller and undulatory movement is turning radius and speed. Fish can turn with a radius 1/10 of their body length, while propeller-driven ships require a much larger radius. Accordingly, the turning speed of fish is much faster than ships. Beyond manoeuvrability, the driving efficiency in biological swimmers also show more improvement over man-made systems [23.81].

To achieve fish-like swimming motion, various mechanisms have been employed such as linkage mechanisms and compliant mechanisms. Barrett first proposed a RoboTuna by using six servo motors and eight linkages [23.71]. Morikawa et al. built a robotic fish mimicking the caudal musculo-skeletal structure of a tuna with two rubber pneumatic artificial muscles and a multijoint bending mechanism [23.82]. A robotic dolphin was designed with four links and six servo motors to mimic the dorsoventral movement of a real dolphin [23.83]. Low developed a fish robot to generate arbitrary undulating waveforms, by connecting ten servo motors in series by linking them with sliders [23.74]. Liu and Hu developed a robotic fish mimicking the body motion of carangiform fish by using three servo motors on each joint, as shown in [VIDEO 431](#) [23.72]. Yang et al. presented Ichthus V5.5 by using 3-DOF serial link-mechanism with servo motors on each joint for propulsion, as shown in [VIDEO 432](#). Ichthus V5.5 has

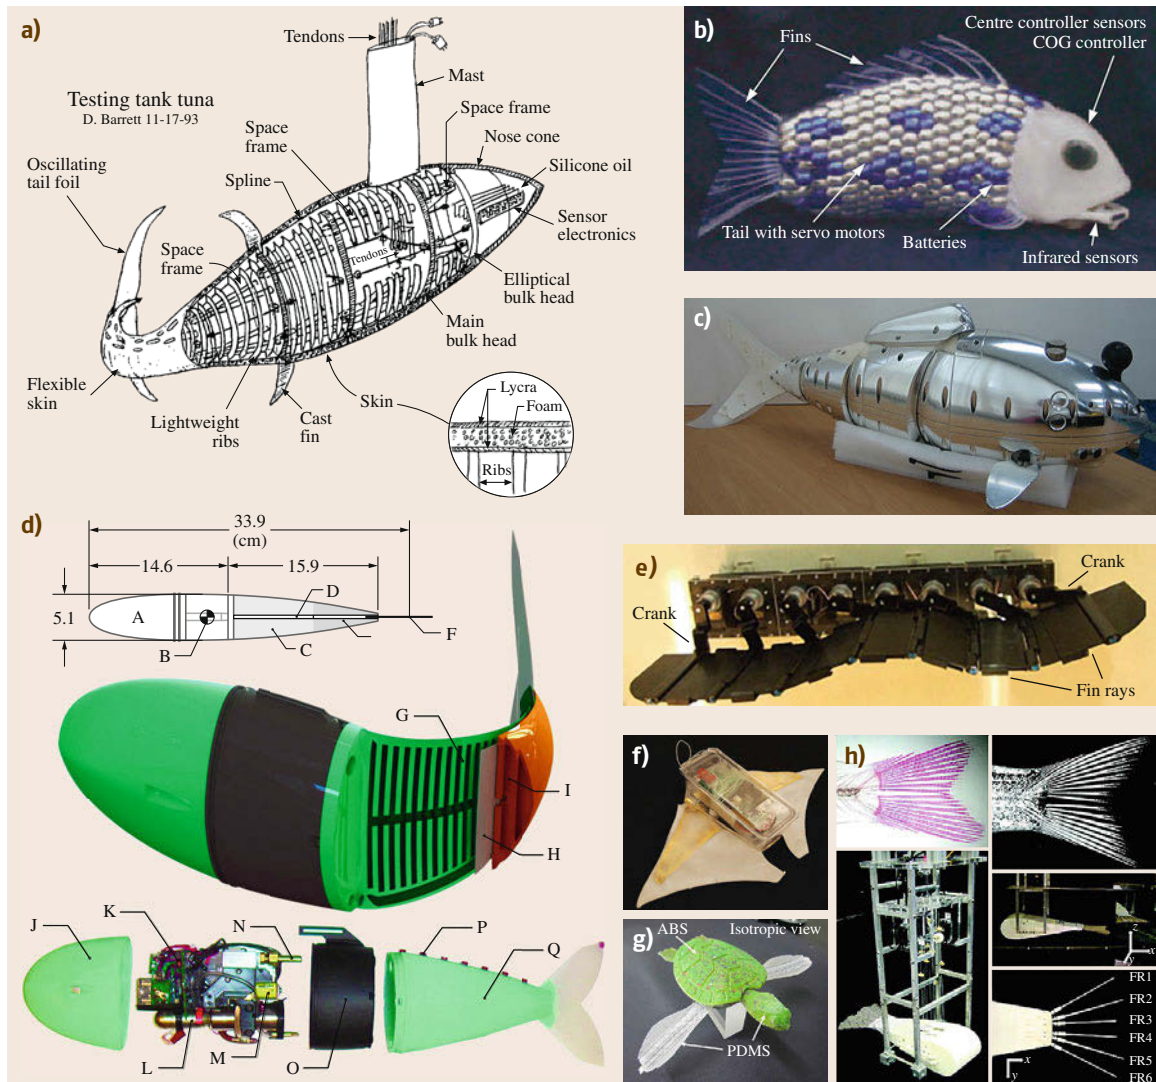

Fig.23.15a–h Design of robotic fin (a) Robo Tuna (after [23.71]), (b) G9 serise robotic fish (after [23.72]), (c) Ichthus (after [23.73]), (d) Undulating robotic fin rays (after [23.74]), (e) Soft robotic fish (after [23.75]), (f) Robotic mata ray (after [23.76]), (g) Turtle-like swimming robot (after [23.77]), (h) Robotic fin rays (after [23.78])

several sensors to navigate autonomously in the real environment such as rivers [23.73].

Beyond linkage mechanisms, several researchers have employed compliant materials in their designs to make the undulatory motion without complicated linkage structures. *Salumäe* and *Kruusmaa* implemented swimming kinematics of a trout by simply adjusting the compliance of a flexible fin with a single actuator [23.84]. *Alvarado* and *Yousef-Toumi* designed a robotic fish with a simple and robust mechanism, using a compliant body that was approximated by a continuous cantilever beam to generate a fish-like oscillating motions [23.85]. This simple design achieved

biomimetic locomotion using only one servomotor, while most other robotic fish use several motors to achieve biomimetic modes of swimming. *Marchese* et al. employed a compliant body with embedded actuators and used a novel fluidic actuation system that drives body motion, as shown in [VIDEO 433](#) [23.75]. *Park* et al. presented a guideline for optimizing the fin to maximize the thrust generated by a compliant fin. The *half- π phase delay* condition describes the condition that the thrust is maximized regardless of the shape of the fin, driving frequency, and amplitude. They also presented a variable-stiffness flapping mechanism to improve the performance of a compliant fin while

Fig.23.16a,b Escapement cam mechanism (a) Grillo (Ver.1) (after [23.86]) and (b) 7 g jumping robot (after [23.87])

the operating conditions change [23.88]. Tendons were used to vary the stiffness and the attachment point is determined based on the anatomy of a dolphin's fluke. Several fish robots that use smart actuators to create undulating motion have also been investigated [23.89]. Wang et al. embedded shape memory alloy (SMA) wire actuator to create flexible bending and investigated the musculature of a cuttlefish fin to aid the design of the biomimetic fin [23.90]. Chen et al. mimicked manta ray by using ionic polymer-metal composite (IPMC) as artificial muscles. They embedded an IPMC muscle in each pectoral fin and a passive PDMS membrane to lead to an undulatory flapping motion on the fin, as shown in [VIDEO 434](#) [23.76]. Kim et al. [23.77] used a smart soft composite (SSC) structure to generate bending and twisting motions in a simple, lightweight structure. Lauder et al. designed a robotic fish caudal fin with six independently moving fin rays based on the anatomy of bluegill sunfish and presented that the cupping motion produced greater thrust than others such as W-shaped, undulation, and rolling [23.78]. They used five different sets of fin rays and measured thrust by varying the motion program. In addition, Lauder et al. used a flexible plastic foil to explore the effects of changing swimming speed, foil length, and shape of the foil-trailing edge on undulatory locomotion [23.91].

23.3.7 Jumping

In nature, many animals use jumping as a locomotion strategy. Jumping has the advantages of overcoming large obstacles and avoiding predators quickly and increasing the chances of survival. Robots also experience challenges in overcoming obstacles larger than the characteristic dimension of the robot. To find solutions for this, many researchers have developed jumping robots inspired by nature.

The jumping process requires large amounts of energy to be released instantaneously. However, muscle has limited reaction speed – achieving a maximum acceleration of 15 m s^{-2} . Therefore, many small creatures, such as insects, have adapted special elastomers for energy storage to generate large accelerations in-

stead of using muscles. On the other hand, most large creatures, such as human that have relatively long legs, primarily use large muscles that can generate sufficient large force to swing long legs quickly.

In small-scale jumping, to achieve large instantaneous acceleration, the jumping process has two steps: 1) slow energy storage and 2) rapid release of the stored energy. Escapement cam mechanism is widely used to achieve these two steps. It consists of a spring, a radius varying cam, a motor, and a gearbox for torque amplification. The motor rotates the cam slowly, but powerfully, toward the direction of compressing or extending the spring. At the final portion of the cycle, the cam's radius returns to the initial state instantly, releasing the spring causing the robot to jump. Grillo (Ver.1) (in [VIDEO 278](#)) [23.86] and a similar 7 g jumping robot (in [VIDEO 279](#)) [23.87] use this escapement cam mechanism (Fig. 23.16).

A toothless gear mechanism is similar to the escapement cam mechanism. The main differences are that the toothless gear mechanism uses an incomplete gear instead of a change in the cam shape. The motor actuates the incomplete gear, and the gear actuates a transmission to compress or extend a spring. When the

Fig.23.17a,b Toothless gear mechanism (a) Grillo (Ver.2) (after [23.92]), (b) Mini-Whig (after [23.93])

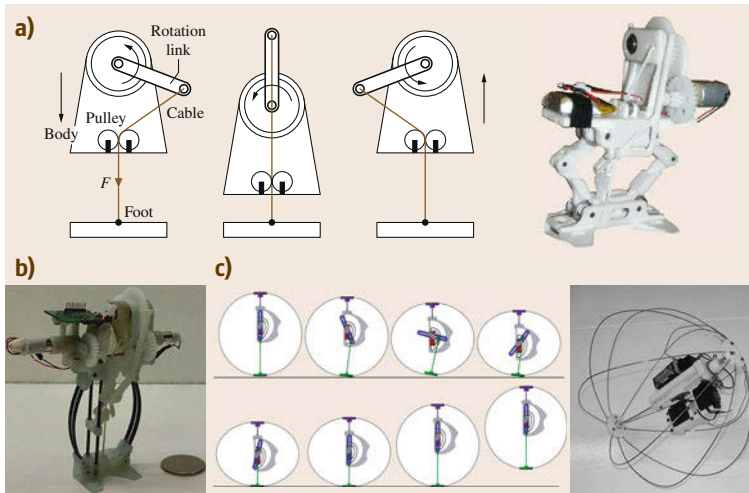

Fig. 23.18a–c Other escapement mechanism (a) MSU Jumper (after [23.94]), (b) MSU Jump-runner (after [23.95]), (c) Jollbot (after [23.96])

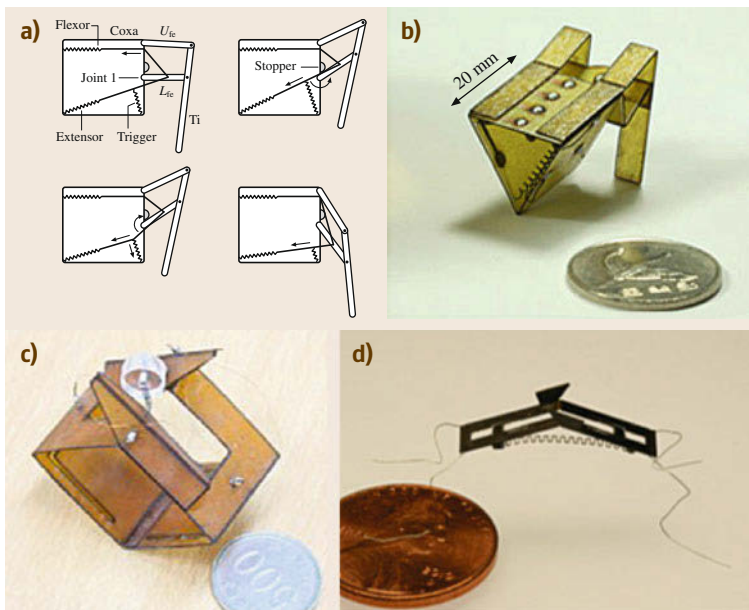

Fig. 23.19 (a) Torque-reversal mechanism, (b) Flea-inspired catapult mechanism (after [23.97]), (c) Simplified flea-inspired catapult mechanism (after [23.98]), (d) Jumping robotic insect (after [23.99])

transmission passes the toothless gear part, the transmission returns to the initial position and the stored energy is released instantly. Examples of robots using toothless gear mechanisms include Mini-Whigs [23.93] and Grillo (Ver.2) [23.92] (Fig. 23.17).

These two click mechanisms, the escapement cam mechanism and the toothless gear mechanism, are commonly used for jumping mechanisms, but other methods have also been developed (Fig. 23.18 and VIDEO 280). The catapult mechanism of MSU Jumper [23.94] and MSU Jump-Runner [23.95] is similar to the escapement cam mechanism, except for the absence of a cam. Instead of using a cam, it uses a one-way bearing. This mechanism can be separated in two

parts based on the critical point in the jump cycle. Before passing the critical point, the one-way bearing cannot rotate freely, so it rotates to the direction of energy storage. On the other hand, after passing that point, it can rotate freely and release the stored energy for jumping. The catapult mechanism in Jollbot [23.96] is similar to the mechanism in the MSU Jumper. Its structure's slit acts like a one-way bearing.

A flea-inspired catapult mechanism [23.97] is different from aforementioned catapult mechanisms (Fig. 23.19 and VIDEO 281). It consists of three SMA coil springs: (1) Flexor, (2) Extensor, and (3) Trigger. The SMA is activated by heat induced from applied current. The flea catapult mechanism begins by activating

Fig. 23.20 An asymmetric robotic catapult jumping robot (after [23.100])

the flexor that folds the leg. Then, the extensor is activated. Because the direction of the torque generated by the extensor force is in the folding direction, the leg does not move and energy is stored in the extensor SMA coil spring. After energy is storage, activation of the trigger attached to the extensor pulls the extensor until it passes the joint. As a result, the direction of the torque generated by the extensor is reversed and the robot starts to jump. This mechanism uses muscle-like actuators to create the torque reversal mechanism, which enables simple design. Variation of the torque reversal mechanisms have been developed with lesser number of actuators but maintaining the same biological principle: the simplified flea-inspired catapult mechanism [23.98] and the jumping robotic insect [23.99].

An asymmetric robotic catapult jumping robot [23.100] also has a unique catapult mechanism (Fig. 23.20). It utilizes buckling in a compliant beam to jump. It consists of a main frame, an elastic strip and a motor. The elastic strip is connected to the main frame with a free rotational joint that can rotate from 0° to 180° and is connected to a motor that can control the rotation angle. When one of the elastic strip's ends is fixed to the main frame, adjusting the angle of the other end can be in a snap-through buckling shape. This can produce bidirectional jumps, but the buckling modes are different on either side.

Jumping mechanisms for microrobots [23.101] have been built using microelectromechanical systems

(MEMS) manufacturing methods to create a silicon body, silicon leg, and a series of PDMS springs (Fig. 23.21a). This mechanism consists of two rigid bodies connected by PDMS springs and is activated by an external force. The robot includes only the mechanisms required to demonstrate a jump. The actuation combined elastomer mechanism is shown in Fig. 23.21b [23.101]. It used chevron actuators. These actuators are used to linearly pull and release the PDMS spring embedded into an etched silicon structure for jumping. The mechanism's PDMS springs are designed

Fig. 23.21 (a) Microrobot (after [23.101]), (b) a colored SEM image of the actuated mechanism (after [23.101])

Fig. 23.22 (a) Pneumatic artificial muscles arranged like bi-articular muscle, (b) Mowgli (after [23.102])

to be similar to resilin – the elastomer that appears in insects [23.101].

In large-scale jumping, to overcome muscle’s limited speed, large animals use their long legs or special arrangements of muscles and bones such as *bi-articular muscles*. They are muscles that work on two joints. In a mechanical linkage that is composed of bi-articular muscle and bones, the two joints affect each other. During the jumping process, these conditions can be helpful for generating the optimum force. The large jumping robot *Mowgli* uses long legs and pneumatic artificial muscles that are arranged like bi-articular muscle and it can be seen in Fig. 23.22 and in VIDEO 285 [23.102].

Specifications of the jumping robots are summarized in Table 23.1.

23.3.8 Gripping and Perching

In nature, insects and animals climb various kinds of terrains – from flat and smooth to wavy and rugged surfaces. Some animals evolved in a way that passively adapts to unstructured environments to reduce the energy consumption and control complexity. From the view point of robotics, these properties have the potential to increase energy efficiency and reduce system complexity. Therefore, many researchers have employed such mechanism to gripping and perching devices.

Hawkes et al. developed a mechanism that allows large patches of directional dry adhesives to conform to the topology of the surfaces they are in contact with [23.103]. The mechanism uses a rigid tile supported by a compliant material loaded by an inextensible tendon – inspired by the tendon system and the fluid-filled sinus in gecko toes. This mechanism permits the adhesive to make full contact with the surface and have uniform loading despite significant errors in alignment. *Hawkes et al.* also developed a gasper for landing of microair vehicles and grappling objects in space using gecko-inspired directional adhesives, as shown in VIDEO 413 [23.104] (Fig. 23.23).

There are several devices and robots that employ microspines for grasping rough surfaces easily seen in nature. *Kim et al.* proposed arrays of miniature spines that catch opportunistically on surface asperities [23.55]. *Desbiens et al.* proposed a small and unmanned aircraft that can land, perch and take off from vertical surfaces, as shown in VIDEO 412 [23.105] inspired by squirrels that reduce their horizontal velocity up to 60% prior to impact to distribute impact over all four limbs. *Spenko et al.* developed a hexapedal climbing robot using rows of toes having microspine [23.56]. *Parness et al.* also employed 16 carriages, each of which contains 16 microspines that conform to mm-scale and below, as shown in VIDEO 414 [23.106] (Fig. 23.24).

Trimmer et al. employed a passive gripping method found in caterpillars [23.107]. Caterpillars use their re-

Table 23.1 Specifications of the jumping robots

Robot	Actuator	Length	Weight	Jumping height	Initial velocity
7 g jumping robot [23.87]	Motor	5 cm	7 g	1.4 m	5.9 m/s
Grillo(Ver.1) [23.86]	Motor	5 cm	15 g	–	1.5 m/s

tractor muscles to release the grip, which means that they do not consume any energy during gripping. Like the caterpillar, Trimmer et al. designed the grippers so that gripping is released when the SMA spring actuator is activated. Jung et al. proposed an underactuated

mechanism based on flexural buckling [23.108]. The flexural buckling mechanism is inspired by the soft cuticle of a caterpillar's feet, which largely deforms depending on the shape of the contacting surface. The large deformation in the engineered device, flexural

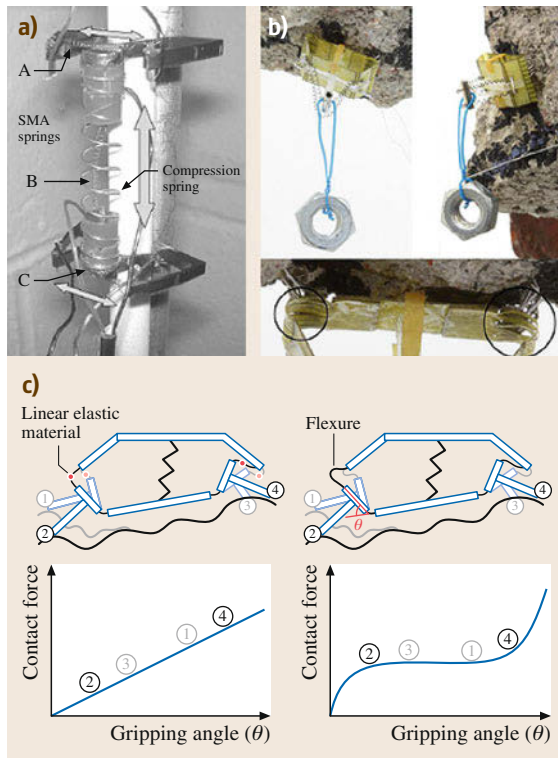

Fig. 23.25 (a) Passive gripping system (after [23.107]), (b) caterpillar-inspired underactuated gripper and (c) constant force region by flexural buckling (after [23.108]) ◀

easily be scaled up or down depending on required scale. [VIDEO 409](#) shows the small and large scale gripper that can achieve adaptive grasping (Fig. 23.25).

The octopus performs crawling movements with the same limbs used for grasping and manipulation, as shown in [VIDEO 411](#). Calisti et al. proposed an octopus-inspired solution for movement and manipulation [23.109]. To implement octopus-like motion, they employed a steel cable for elongating and shortening and fiber cables for bending, which is inspired by the longitudinal muscles found in an octopus shown in Fig. 23.26.

Kim et al. developed flytrap-inspired high-speed gripper, as shown in [VIDEO 410](#) [23.110]. Flytraps achieve fast capturing by using the bistable structural characteristic of its leaf. To achieve similar bistability, Kim et al. used asymmetrically laminated carbon fiber reinforced prepreps (CFRP). They also utilized a deformable surface having kinematic constraints, which constrain the curvature of the artificial leaf. Therefore, the curved leaf can be actuated by bending the straight edge orthogonal to the curve, a process called bending propagation.

Doyle et al. developed an avian-inspired passive perching mechanism for quadrotors for perch-and-stare, as shown in [VIDEO 415](#) [23.111]. Songbirds had evolved to sleep while perching. When they perch on a branch, the tendon connected from the ankle and

buckling with an adequately selected length, provides wide gripping range with a narrow range of force variation. This provides a sufficient number of contacts with even contact forces, enabling adaptive gripping on various surfaces. In addition, design of the gripper can

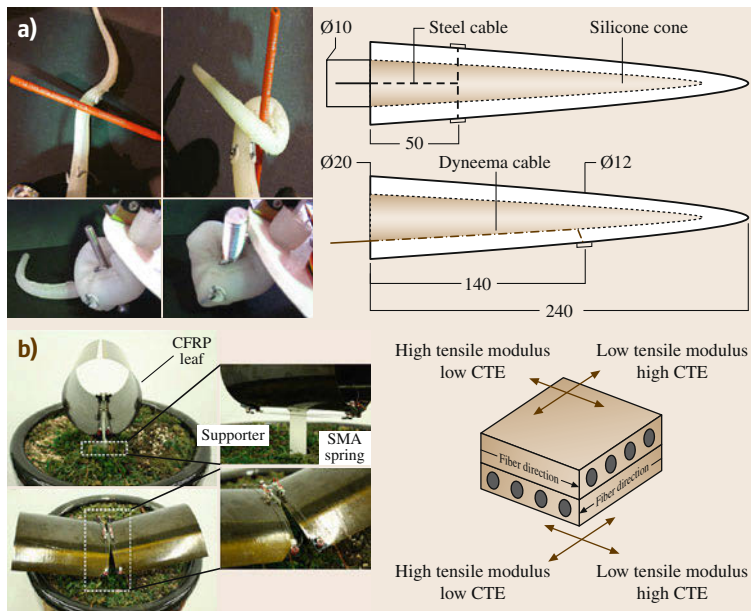

Fig. 23.26 (a) Octopus-inspired manipulation (left) and tendon-driven mechanism (right) (after [23.109]), (b) Flytrap-inspired gripper (left) and Orthogonally laminated CFRP (right) (after [23.110])

Fig. 23.27 (a) Avian-inspired perching mechanism with UAV (left) anatomy and mechanism design (right) (after [23.111]), (b) perching mechanism and process (after [23.112])

the rear side of toe automatically cause the toe to grip the branch. This allows the songbirds to tightly grip the branch without any muscular effort. Inspired by this, Doyle et al. used a four-bar mechanism and a tendon connected from the knee to the ankle and foot to couple landing motion with grasping. Kovač et al. presented

a 4.6 g perching mechanism for microaerial vehicles (MAVs) to make them perch on various walls such as tree and concrete buildings [23.112], as shown in [VIDEO 416](#). To achieve high impact force, the needles snap through as the trigger collides with the target surface (Fig. 23.27).

23.4 Material and Fabrication

23.4.1 Shape Deposition Manufacturing

The fundamental concept of shape deposition manufacturing (SDM) is layered molding manufacturing with CNC machining process. It not only create complex 3-D shapes rapidly, but also enables high precision finishing and large design flexibility. This concept is initially proposed by Weiss et al. [23.113]. Figure 23.28a shows the steps of the SDM process and Fig. 23.28b shows fabrication result [23.114]. After depositing support material, the support was fabricated by CNC machining to make high precision surface. Li et al. shows

that it is possible to embed a various functional material such as sensors to the structure [23.115] and Marra et al. show that this process can be used in the fabrication of scaffolds for bone tissue engineering [23.116].

In 1999, the SDM process was first used for robot design by Bailey et al. [23.114]. Robot design methods based on the SDM process have advantages that it does not need complex assembly or connecting methods, and it can embed sensors and actuators directly into the body structure. In other words, the structure is build and assembled at the same time, and this

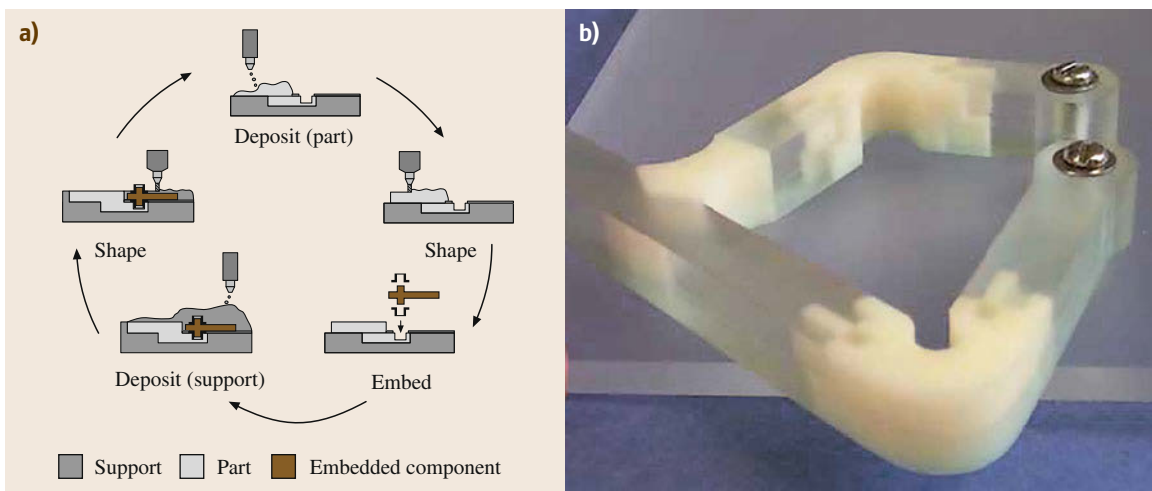

Fig. 23.28a,b Shape deposition manufacturing (a) Process, (b) result of SDM process for robot mechanism design (after [23.114])

Fig. 23.29 Hexapedal robot built by SDM process (after [23.117])

Fig. 23.30 Robotic gripper built by SDM process (after [23.118])

characteristic leads to enhanced manufacturability in small-scale applications. To build a desired mechanism, the author used multiple cycles of material deposition and shaping as shown in Fig. 23.28a. Multiple materials were used in fabrication to create variable characteristic to each functional part. More flexible material was used for joints and rigid material was used for links. The flexible components are not only used as articulated joints, but also as dampers and springs to control the impedance of a mechanism. *Binard et al.* suggested a design framework for the SDM

process for mechanism design, making more multi-farious applications possible [23.119]. Figure 23.29 shows *Sprawlita*, a hexapedal robot fabricated based on the SDM process. Using the SDM process, actuators and wires are embedded in the body structure, resulting in robust performance and minimal manual assembly operations [23.117]. Robotic grippers can also be made by the SDM process (Fig. 23.30) [23.118]. All of joints, links, and sheath for the actuating wire were fabricated and assembled simultaneously. Embedded sensors are also possible. Force sensors embedded in the fingertips of a robotic SDM gripper have been demonstrated [23.120]. Using a soft base material for the robot, it is also possible to design a human-friendly SDM robot [23.121].

23.4.2 Smart Composite Microstructures

In the late 1990s, researchers at the University of California, Berkeley began a project to create a robotic insect capable of sustained autonomous flight – the micromechanical flying insect was born [23.122]. Among the many challenges for this project, how to manufacture and what materials should be used for structures, mechanisms, and actuators were primary concerns. Recognizing the lack of a viable *meso-scale* manufacturing method, the team lead by Fearing attempted multiple techniques including folded triangular stainless steel beams [23.123] and eventually settled on multilayer composites [23.124]. In this paradigm, later called smart composite microstructures (SCM) [23.50], layers of materials are machined, aligned, and laminated to form a quasi-two-dimensional (quasi-2-D) laminate. The choice of materials, 2-D layer geometries, and order of the layup allows the user to create an array of rigid components separated by compliant flexures. This composite laminate, later called a *standard linkage layer* can then be folded into 3-D shapes and mechanisms.

The SCM process presents a new paradigm of design and fabrication for developing small-scale robots. Planar fiber-reinforced prepreg (FRP) and flexure hinges replace conventional links and joints in the robot mechanism. The composite laminating process is

Fig. 23.31 Schematic illustration of a single joint unit in SCM and the layup of laminating process (after [23.50])

Fig.23.32a–c Spherical five-bar linkage structure created by the SCM fabrication process (after [23.52]). (a) The pattern design of a rigid face sheet, (b) laser-cut and cured microcomposite sheet before folding, (c) SCM spherical five-bar linkage for transmission of MFI

Fig.23.33a–d Various generations of MFI. (a) Wing transmission made of steel face sheet (after [23.123]). (b) Thorax mechanism with five-bar spherical linkage SCM (after [23.124]). (c) The Harvard robotic fly is capable of flapping-wing liftoff (after [23.50]). (d) The Harvard robotic fly is the first robotic insect capable of unconstrained controlled flight (after [23.125])

adopted instead of conventional machining and assembly processes which are difficult to apply to building a small-scale robot mechanism. Figure 23.31 shows a single unit of the links and the flexure hinge joints which are the key building blocks of the SCM process [23.50]. The flexure joint is a polymer film that can be bent easily and eliminating friction losses that are the dominant cause of reduced efficiency in small-scale robot mechanisms.

Rigid face sheets of fiber-reinforced composites sandwich polymers and joints are created at the gap between face sheets. The resulting quasi-2-D sheets are then folded into 3-D structures. The face sheets of rigid composite materials are carefully patterned to create robot mechanisms. For example, Fig. 23.32a is a 2-D pattern designed for creating a spherical five-bar linkages as shown in Fig. 23.32c. This is the wing

transmission linkage in the early versions of micromechanical flying insect (MFI) [23.52].

Figure 23.33 shows the various versions of the MFI developed using the SCM fabrication process. Figure 23.33a is the early version of a transmission that uses a steel face sheet [23.123]. Figure 23.33b is the next generation of the MFI fabricated using a carbon fiber composite (CF) sheet and polyester film. It has 26 joints, 4-DOF, four actuators, and two wings. CF composites materials improve the performance of MFI thorax structure by reducing the inertia by a factor of three and increasing the resonant frequency by 20% [23.124]. A later version with a 3-DOF transmission (two passive DOF) and a single bimorph PZT actuator as shown in Fig. 23.33c was able to produce sufficient thrust to achieve liftoff [23.52]. Passive dynamics in the thorax structures simpli-

Fig. 23.34 DASH (after [23.8])

Fig.23.35a,b 1:900 scale 1903 Wright Flyer model 14 mm in wing span (after [23.126]). After laminating layout (a), model after folding (b)

fies the design and reduces undesired coupling between the degrees of freedom. Controlled flight is accomplished by separated actuator design shown in Fig. 23.33d. Tethered but unconstrained stable hovering and basic controlled manoeuvres are demonstrated [23.125].

The **SCM** fabrication process can be extended to larger scales by using various sheet materials. Figure 23.34 shows centimetre scale crawling robots that are built using the **SCM** fabrication process with cardboard and adhesive films in place of the composites used in the **MFI**. This new paradigm is fast and inexpensive – both in the materials used and the required infrastructure. Furthermore, novel bio-inspired robot mechanism that produce high performance can be created easily as shown in Fig. 23.34. Figure 23.34a is a small, lightweight, power autonomous running robot, DASH [23.8]. It is capable of running at speeds up to 15 body lengths per second and surviving falls from large heights, due to the unique compliant nature of its structures. The design can be modified easily and achieve high performance with regard to stability, speed, and maneuverability as shown in Fig. 23.34b [23.10].

23.4.3 Pop-Up Book MEMS

In order to streamline the development of high performance and economical robots, many assembly tools have been developed to assist with robot construction at various scales. However, in millimetre-scale robots, many challenges arise in the fabrication process and handling many individual parts for assembly. Pop-up books and paper folding inspire the solution for eliminating the onerous assembly process with small individual parts in the fabrication process of the millimetre-scale robotic structures. Monolithic fabrication using pop-up book-inspired designs enables efficient batch processing starting from multiple layered composites similar to the basic elements used in **SCM**. The carefully designed layers are interconnected and allow folding mechanisms of high complexity. Once folding ensues, the complex 3-D structures are created by parallel mechanisms created in the thickness

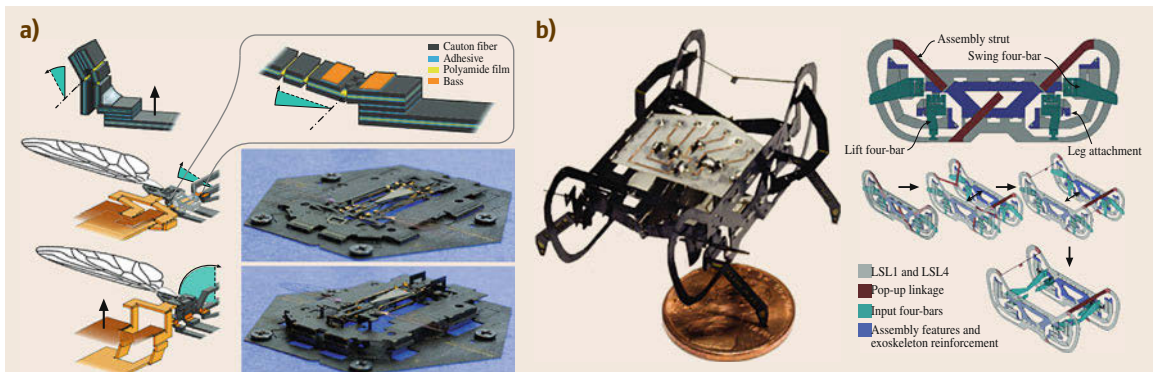

Fig. 23.36 (a) Mobee, monolithic design of **MFI** [23.127], (b) HAMR-VP, a 1.27 g quadrupedal microrobot manufactured using the **PC-MEMS** and pop-up assembly techniques (after [23.16])

Fig. 23.37 Young's modulus for various materials (after [23.128] which was also adapted by Autumn et al. in [23.63])

of the laminate. Figure 23.35 presents a pop-up structure of 1:900 scale 1903 Wright Flyer model, 14 mm in wing span [23.126]. The model consists of six rigid CF composite layers, seven adhesive layers, and two polymer flexure layers. Multiple rigid-flex folding layers are stacked and selectively bonded. The idea is previously applied to microelectric mechanical systems (MEMS) process. Combining this idea and pop-up book designs, the fabrication process is developed for building micro robotic systems including robot structures and actuators.

Figure 23.36 shows two examples that are designed and fabricated by the pop-up book MEMS process. Figure 23.36a is the Mobee (Harvard robotic fly using the monolithic pop-up book MEMS design methods) [23.127]. In [VIDEO 398](#), it demonstrates how the pop-up book MEMS process enables mass production by parallel manufacturing on a single sheet and reduces entire fabrication time by eliminating onerous assembly tasks. Figure 23.36b is a small-scale quadruped crawling robot designed by pop-up book MEMS techniques. This device demonstrates how complex millimeter-scale robot structures are capable of pop-up assembly [23.16]. Twenty-three material layers are cut by precision laser machining and laminated with selective adhesion. After pop-up, the body frame is created and other components such as a circuit board and actuators are bonded on the frame.

23.4.4 Other Fabrication Methods

In nature, animals use soft parts of their body for generating locomotion, morphing configuration, and adapting to the environment. In order to maximize the utility of their compliance, some bio-inspired robots are primarily composed of soft materials such as fluids, gels, granules, and soft polymers. With respect to compliance, soft materials vary with a wide range of elastic (Young's) modulus [23.128] (Fig. 23.37). Therefore, bio-inspired robots should be built by different fabrication methods depending on their constituent materials.

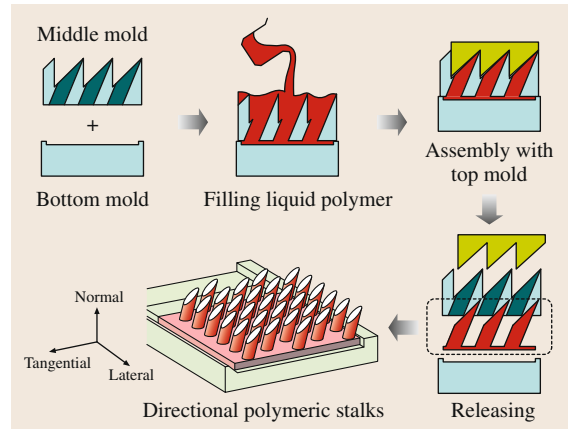

Fig. 23.38 Manufacturing process of directional adhesion pad (after [23.58])

Soft Lithography

Soft lithography was originally proposed for micro- and nanostructure manufacturing in 1998 [23.129]. Early soft lithography used an elastomeric stamp with patterned relief structures on its surface to generate desired patterns and structures. In bio-inspired robotics, for example, a directional adhesion pad inspired by a gecko foot's microscale adhesion spines was developed by a similar fabrication method to soft lithography [23.58] (Fig. 23.38).

Advances of convenient, effective and low-cost soft lithography allowed it to be utilized not only in the micro and nano scale in bio-chemical fields, but also in macro-scale robotics. Moreover, development and popularization of additive manufacturing process using 3-D printers which can design molds with various shapes easily and rapidly have helped soft lithography to be applied in robotics. Soft lithography has become a representative manufacturing method for bio-inspired soft robots since soft lithography was first applied to manufacturing bio-inspired soft robots [23.130–133] (Fig. 23.39). In soft lithography for bio-inspired soft robots, uncured elastomeric polymers, such as PDMS or EcoFlex, are poured into a mold designed with

configuration of the structure. After curing, the soft materials form a structure containing multiple air chambers and pneumatic channels. Such kind of structure is so-called a pneumatic network (PneuNet) or bending fluidic actuator (BFA).

This structure allows the robots to generate sophisticated locomotion such as gripping, walking, and crawling as shown in Fig. 23.40. In addition, extra embedded channels can control the flow of a dyeing solution so that a soft robot can camouflage by changing body color to match the color of the surroundings [23.135]. The actuation or locomotion of robots manufactured by soft lithography depends on the elastic modulus of materials and the geometry and position of air chambers [23.136].

Furthermore, soft lithography in robotics has advanced by mixing different kind of materials. By embedding sheets or fibers into elastomers, an actuator has asymmetric compliance which allows the structure to be flexible but not extensible, so that the actuator can generate a wide range of motions such as bending, extension, contraction, twisting, and others [23.137] (Fig. 23.41). By embedding magnets into elastomers, a soft robot can attach, detach, and easily align modules that have a unique function per each module depending on the task [23.138].

Fig. 23.39 Soft lithography of pneumatic network (PneuNet) or bending fluidic actuator (BFA) (after [23.130, 133, 134])

Fig. 23.40 Bio-inspired soft robots and actuators manufactured by soft lithography (after [23.130, 131, 135, 136])

To overcome a slow actuation, which is a typical issue for soft robots, the design of segmented air chambers divided by slits was introduced as an alternative soft actuator [23.139]. As a result, a fast PneuNet structure had high rate of actuation, improved 25 times relative to the slow PneuNet actuators. Also, a reduced change of volume minimizes fatiguing the materials, and thus the durability improves to a level that the actuator does not fail within a million cycles of full bending.

Actuator Embedded Molding

Bio-inspired soft robots potentially have infinite degrees of freedom and the nonlinearity of soft materials creates difficulty in generating desired postures and motion. Actuator-embedded molding is commonly used to manufacture the soft structure for bio-inspired robots. In actuator-embedded molding, the design considerations are the type of the actuator and the actuator's location and direction in the soft structure. For an example of a bio-inspired robot using actuator-embedded molding, a turtle-like swimming robot was created using a smart soft composite (SSC) structure to create bending and twisting deformation [23.77] (Fig. 23.42). The SSC structure consists of an actuator-embedded layer as an active component, a patterned layer as a passive component, and a soft matrix as the body as shown in Fig. 23.42. The angle of the patterned layer determines the bending direction passively, and the actuator-embedded layer generates deformation. The soft matrix helps to deform the structure continuously. Widely used

Fig. 23.41a–e Programmable paper-elastomer composites-based pneumatic actuators by using soft lithography (after [23.137])

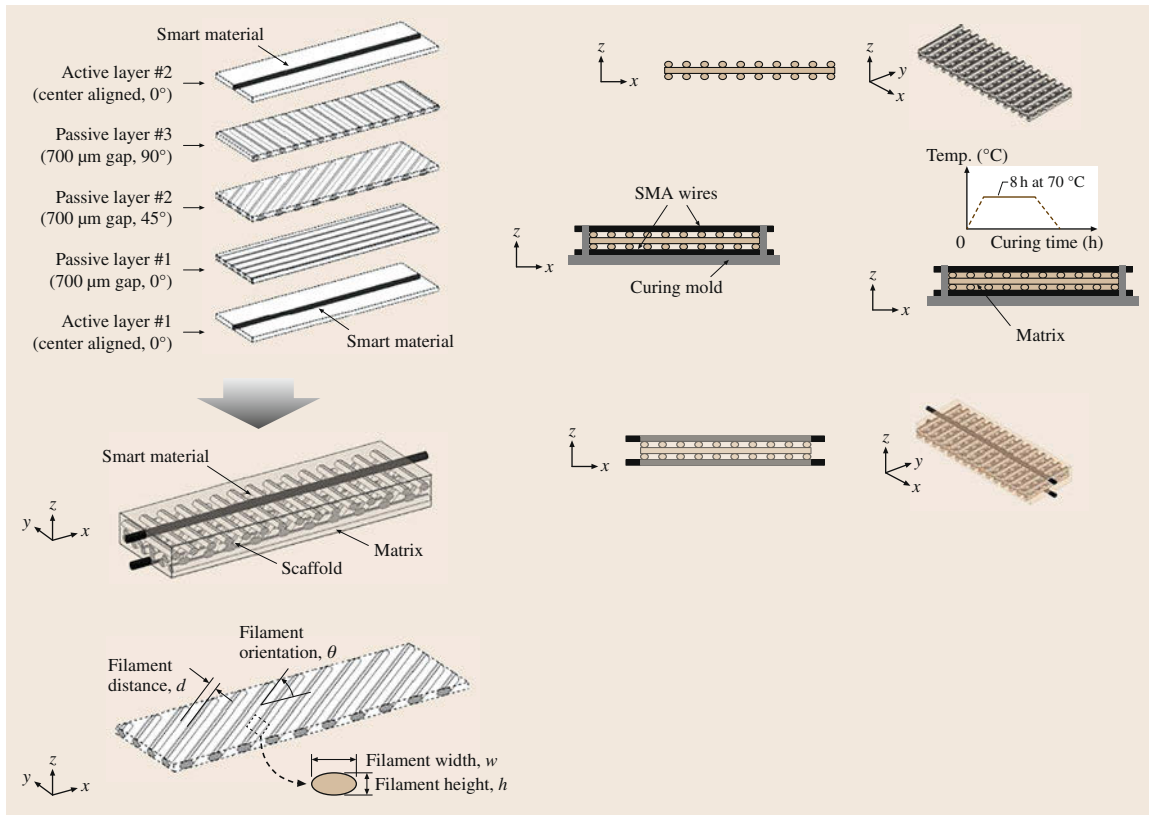

Fig. 23.42 Actuator-embedded molding for the SSC structure actuator (after [23.77])

actuators in the actuator embedded molding are wires including common wires connected with servo motors and shape memory alloys (SMA) [23.25, 77, 140].

Additive Manufacturing

Additive manufacturing or 3-D printing is a rapid prototyping (RP) process of manufacturing a 3-D solid structure of any configuration through sequential layering from a digital CAD model. Since the 1980s, various types of additive manufacturing have been developed: solid-based processes such as fused deposition modeling (FDM), photo curable liquid polymer-based processes such as stereolithography (SLA), and powder-based processes such as selective laser sintering (SLS).

Evolving the technology of 3-D printers, soft material deposition and even hybrid deposition of different materials with different stiffnesses are available. Thus, soft structures can be built at once, and products using hybrid deposition can have features of rigidity and softness at the same time. For example, a highly deformable 3-D printed soft robot was developed [23.141]. This robot body was printed by using a multimaterial printable 3-D printer (Objet Connex 500TM 3-D printer) with two materials: one is a soft rubber-like Objet TangoBlackPlusTM and another is a hard polypropylene-like Objet VeroWhitePlusTM. These two materials have different friction coefficients; thus, the robot can switch friction with the ground on its edge by bending the body.

23.5 Conclusion

Biomimetic robotics attempt to create devices that are capable of various types of effective interaction with natural environment, e.g., locomotion and manipulation, by using the principles of nature. Nature is full of

surprising types of movements that enables insects and animals to survive by escaping from danger or hunting for food. In this chapter, we have presented robots that attempt to recreate these feats by understanding the un-

derlying principles, deriving an engineering design, and fabricating them with novel methods. In recent years, engineers have succeeded in recreating insects and animals that show amazing capabilities such as climbing walls like a gecko, hovering like a fly and climbing trees like a snake. These robots have been developed to understand nature, and also to be used as tools for surveillance, information gathering, and rescue operations. However, many of these robots are still in the basic research phase and are not yet ready for everyday use.

The key open research issues remain in the broad areas of materials, fabrication, actuation, and power. Composites and polymers, together with novel fabrication methods, have enabled various novel biomimetic robots. Development of these new material and fabrication has been one of the key enabling technologies, and further development of these technologies will certainly contribute to more mature biomimetic robots. Actuation and power still remain the bottleneck of many biomimetic robots. DC motors are the actuators of choice for many biomimetic robots, and with novel transmission design, DC motors can create motions required by the robots. However, DC motors are inefficient for small-scale biomimetic robots. Although artificial muscle actuators that are based on

shrinkage or expansion of material, e.g., shape memory alloys, IPMC, electro-active polymers and shape memory polymers, promise to give robots capabilities similar to creatures that use biological muscles even at small scales. However, many issues related to robustness, efficiency, and power limit the capabilities of robots that use these actuators. Limitations of these actuators should be carefully considered to match the desired application. Development of new artificial muscle actuator that can emulate biological muscles – without the drawbacks of current actuators – is needed to open up a new era for biomimetic robots. Batteries also limit the capabilities of current biomimetic robots compared to their biological counterparts in terms of size and operation time. Development of energy-harvesting technologies together with new battery chemistries and manufacturing methods will enable longer operation time, which will contribute to realizing wider applications for biomimetic robots. Overall, biomimetic robot design is one of the most challenging areas of robot design since it requires development of various technologies to mimic the structure and function of natural systems. Therefore, development of biomimetic robots can have broader impact in many areas of engineering and science, and should be seen as a platform for various convergent technologies.

24. Wheeled Robots

Woojin Chung, Karl Iagnemma

The purpose of this chapter is to introduce, analyze, and compare various wheeled mobile robots (WMRs) and to present several realizations and commonly encountered designs. The mobility of WMR is discussed on the basis of the kinematic constraints resulting from the pure rolling conditions at the contact points between the wheels and the ground. Practical robot structures are classified according to the number of wheels, and features are introduced focusing on commonly adopted designs. Omnimobile robot and articulated robots realizations are described. Wheel–terrain interaction models are presented in order to compute forces at the contact interface. Four possible wheel–terrain interaction cases are shown on the basis of relative stiffness of the wheel and terrain. A suspension system is required to move on uneven surfaces. Structures, dynamics, and important features of commonly used suspensions are explained.

24.1 Overview

Wheeled robots have been widely used to achieve mobility because there are many advantages including the simple structure, energy efficiency, fast speed, low fabrication cost, and so forth. The purpose of this chapter is to provide a general description of wheeled mobile robots, to discuss their properties from the mobility point of view, to describe the most commonly encountered realizations of such robots, and to explain wheel–terrain interaction models and suspension systems.

The chapter is organized as follows: Sect. 24.2 is devoted to the characterization of the restriction of robot motion induced by these pure rolling conditions. We first describe different types of wheels used in the construction of mobile robots and derive the corresponding kinematic constraints. This allows us to characterize the mobility of a robot equipped with several wheels of these different types, and we show that these robots can be classified only into five categories, corresponding to two mobility indices.

In Sect. 24.3, we present several realizations of wheeled mobile robots by the use of various types of wheels. Structures and features of widely used wheel mechanisms are explained. Design issues of wheeled robots include capability of omnidirectional movement, fabrication cost, difficulty of control, and terrain traversability.

Section 24.4 explains wheel–terrain interaction models. It is shown that four possible wheel–terrain interaction cases can be obtained according to the relative stiffness of the wheel and terrain. The presented analytical models are broadly suitable for analysis, simulation, design, and control purposes.

Section 24.5 presents suspensions for wheeled robots. A suspension is a system of linkages, springs, dampers, and actuators that governs the relative motion between a robot's wheels and body. Suspension mechanisms are useful when driving over uneven surfaces. Common methods for modeling passive and semiactive suspensions are presented. The analysis of these models allows for principled selection of springs, dampers, and active or semiactive actuators that form the basis of nearly all wheeled robot suspensions.

Finally, some concluding remarks are given in Sect. 24.6.

24.2 Mobility of Wheeled Robots

In this section, we describe a variety of wheels and wheel implementations in mobile robots. We discuss the restriction of robot mobility implied by the use of these wheels and deduce a classification of robot mo-

bility allowing one to characterize robot mobility fully, whatever the number and type of the wheels.

24.2.1 Types of Wheels

In order to achieve robot locomotion, wheeled mobile robots are widely used in many applications. In general, wheeled robots consume less energy and move faster than other locomotion mechanisms (e.g., legged robots or tracked vehicles). From the viewpoint of control, less control effort is required, owing to their simple mechanisms and reduced stability problems. Although it is difficult to overcome rough terrain or uneven ground conditions, wheeled mobile robots are suitable for a large class of target environments in practical applications. When we think of a single-wheel design, there are two candidates: a standard wheel or a special wheel. A standard wheel can be understood as a conventional tire. Special wheels possess unique mechanical structures including rollers or spheres. Figure 24.1 shows the general design of a standard wheel. Three conditions should be defined for a standard wheel design:

1. Determination of the two offsets d and b
2. Mechanical design that allows steering motion or not (i.e., to fix the wheel orientation or not)
3. Determination of steering and driving actuation (i.e., active or passive drive).

Condition 1 is the kinematic parameter design problem for a single standard wheel. The parameter d can be either 0 or some positive constant. Parameter b is the lateral offset of the wheel and is usually set to zero. In a special design, a nonzero b may be selected to obtain pure rolling contact between the wheel and ground without causing rotational slip at the contact point. However, this is rarely used and we mainly consider the case of zero lateral offset b .

Fig. 24.1a–c The general design of a standard wheel. (a) Side view, (b) front view, and (c) top view

Condition 2 is a design problem for whether the wheel orientation can be changed or not. If the steering axis is fixed, the wheel provides a velocity constraint on the driving direction. Condition 3 is the design problem of whether to actuate steering or driving motion by actuators or to drive steering or motion passively.

If steering motion is allowed, the offset d plays a significant role in the kinematic modeling. For a conventional caster wheel (i.e., an off-centered orientable wheel), there is a nonzero offset d . Point A in Fig. 24.1 indicates the location of the joint connecting the wheel module to the robot chassis. Two orthogonal linear velocity components at point A are obtained by a caster wheel, which results from the steering and driving motions of the wheel module. This implies that a passive caster wheel does not provide an additional velocity constraint on the robot's motion. If a caster wheel is equipped with two actuators that drive steering and driving motions independently, holonomic omnidirectional movement can be achieved because any desired velocity at point A can be generated by solving the inverse kinematics problem.

If the offset d is set to zero, the allowable velocity direction at point A is limited to the wheel orientation. In such a case, the steering motion should not be passive because the wheel orientation cannot be changed passively. However, the driving velocity can be determined passively by the actuation of other wheels. Wheel orientation should be actively steered to the desired velocity direction due to the nonholonomic velocity constraint. This implies that the wheel orientation should be aligned before movement.

In summary, four types of standard wheels are commonly used. First is a passively driven wheel with a fixed steering axis. Second is a passive caster wheel with offset d . Third is an active caster wheel with offset d , where the steering and driving motions are controlled by actuators. An example of caster wheels is shown in [VIDEO 325](#). The fourth is an active orientable wheel with zero offset d , where steering and driving motions are driven by actuators. The structures of each wheel type are shown in Fig. 24.2. The kinematics and constraints of those wheels will be explained in detail in Sect. 24.2.2.

Although standard wheels are advantageous because of their simple structure and good reliability, the nonholonomic velocity constraint (i.e., no side-slip condition) limits robot motion. On the other hand, special wheels can be employed in order to obtain omnidirectional motion of a mobile robot (omnimobile robot), i.e., to ensure three degrees of freedom for plane motion. We consider two typical designs of special wheels: the Swedish wheel and the spherical wheel. Figure 24.3a and [VIDEO 328](#) show the

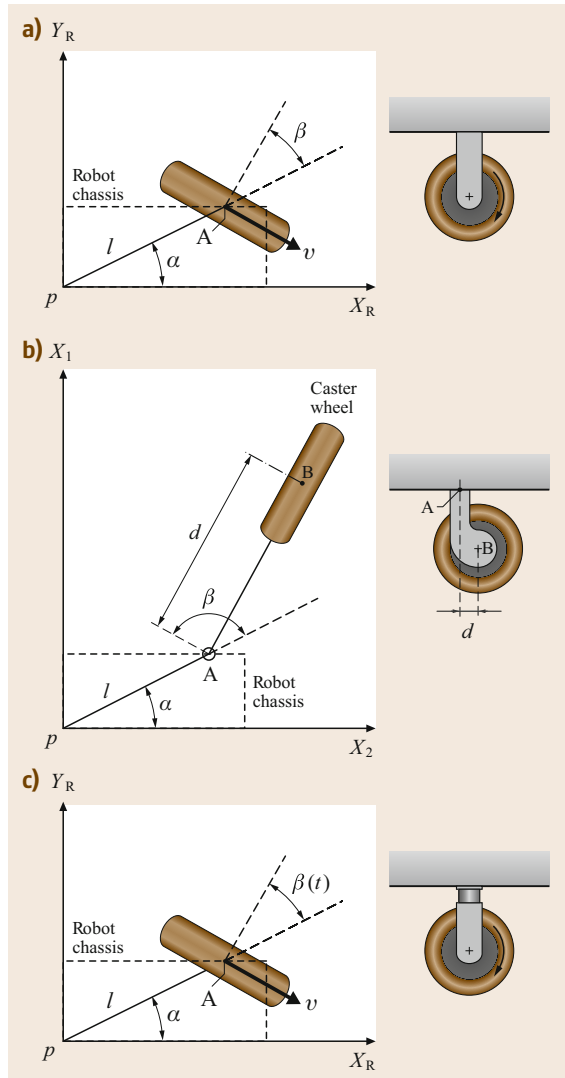

Fig. 24.2a–c Structures of standard wheels. (a) Passive fixed wheel, (b) passive or active, off-centered orientable wheel, and (c) active orientable wheel without offsets

Swedish wheel. Small passive free rollers are located along the outer rim of the wheel. Free rollers are employed in order to eliminate the nonholonomic velocity constraint. Passive rollers are free to rotate around the axis of rotation, which results in lateral motion of the wheel. As a result, a driving velocity should be controlled, while the lateral velocity is passively determined by the actuation of the other wheels. A similar design can be seen in [VIDEO 327](#).

A spherical wheel is shown in Fig. 24.3c. The rotation of the sphere is constrained by rollers that make rolling contact with the sphere. The rollers can be divided into driving and supporting rollers. The sphere is

Fig. 24.3 (a) Swedish wheel, (b) attachment of a Swedish wheel, and (c) spherical wheel (after [24.1])

driven by the actuation of the driving rollers, whereas the rolling contacts provide nonholonomic constraints, and the resultant motion of the sphere module becomes holonomic. This implies that the robot can be moved

with any desired linear/angular velocities at any time. By using the spherical wheel, a holonomic omnidirectional mobile robot can be developed and the robot achieves smooth and continuous contact between the sphere and the ground. However, the design of the sphere-supporting mechanism is difficult and the payload must be quite low due to the point contact. Another drawback is that the surface of the sphere can be polluted when traveling over dirty ground and it is difficult to overcome irregular ground conditions. These drawbacks limit the practical application of the spherical wheel. An example of the use of spherical wheels can be found in [24.1] and [24.2]. The spherical structure can also be applied to special robotic transmissions; examples include the nonholonomic manipulator in [24.3] and the passive haptic system in [24.4].

24.2.2 Kinematic Constraints

We assume, as a first step, that the mobile robot under study is made up of a rigid cart equipped with nondeformable wheels, and that it is moving on a horizontal plane. The position of the robot on the plane is described, with respect to an arbitrary inertial frame, by the *posture* vector $\xi = (x \ y \ \theta)^T$, where x and y are the coordinates of a reference point P of the robot cart, while θ describes the orientation of a mobile frame attached to the robot, with respect to the inertial frame (Fig. 24.4).

We assume that, during motion, the plane of each wheel remains vertical and the wheel rotates around its horizontal axle, whose orientation with respect to the cart can be fixed or varying. We distinguish between the two basic classes of idealized wheels, namely conventional and the Swedish wheels. In each case,

Fig. 24.4 The posture definition of a mobile robot on a plane

it is assumed that the contact between the wheel and the ground is reduced to a single point. The kinematic constraints result from the fact that the velocity of the material point of the wheel in contact with the ground is equal to zero.

For a conventional wheel, the kinematic constraints imply that the velocity of the center of the wheel is parallel to the wheel plane (*nonslip condition*) and is proportional to the wheel rotation velocity (*pure rolling condition*). For each wheel, the kinematic constraints therefore result in two independent conditions. For a Swedish wheel, due to the relative rotation of the rollers with respect to the wheel, only one of the velocity components of the wheel contact point is zero. The direction of this zero component is fixed with respect to the wheel plane and depends on the wheel construction. For such wheels, the kinematic constraints result in only one condition.

Conventional Wheels

We now derive the general form of the kinematic constraints for a conventional wheel.

As shown in Fig. 24.2, there are several variations of the conventional wheel design. First, we focus on the off-centered orientable wheel in Fig. 24.2b. The center of the wheel, B, is connected to the cart by a rigid rod from A (a fixed point on the cart) to B, aligned with the wheel plane. The rod, whose length is denoted by d , can rotate around a fixed vertical axle at point A. The position of A is specified by two constant polar coordinates, l and α , with respect to the reference point P. The rotation of the rod with respect to the cart is represented by the angle β . The radius of the wheel is denoted by r , and its angle of rotation around its horizontal axle is denoted by φ . The description therefore involves four constant parameters: α , l , r , and d , and two variables: $\varphi(t)$ and $\beta(t)$.

With these notations the kinematic constraints are derived as follows.

We make the derivation explicit for the general situation corresponding to a caster wheel (Fig. 24.2b). For fixed or steering wheels one just has to consider either the case $d = 0$ and constant β (fixed wheels), or $d = 0$ and variable β (steering wheels).

First, we evaluate the velocity of the center of the wheel, which results from the following vector expression $\frac{d}{dt}\mathbf{OB} = \frac{d}{dt}\mathbf{OP} + \frac{d}{dt}\mathbf{PA} + \frac{d}{dt}\mathbf{AB}$. The two components of this vector in the robot frame are expressed as

$$\dot{x} \cos \theta + \dot{y} \sin \theta - l \dot{\theta} \sin \alpha + (\dot{\theta} + \dot{\beta})d \cos(\alpha + \beta)$$

and

$$-\dot{x} \sin \theta + \dot{y} \cos \theta - l \dot{\theta} \cos \alpha + (\dot{\theta} + \dot{\beta})d \sin(\alpha + \beta).$$

The projections of this vector onto the direction of the wheel plane, i. e., onto the vector $(\cos(\alpha + \beta - \pi/2), \sin(\alpha + \beta - \pi/2))$ and the vector of the wheel axle $(\cos(\alpha + \beta), \sin(\alpha + \beta))$, are $r\dot{\varphi}$ and 0, respectively, corresponding to the pure rolling and nonslip conditions.

After some manipulations, these conditions can be rewritten in the following compact form.

Pure Rolling Condition.

$$(-\sin(\alpha + \beta) \cos(\alpha + \beta) l \cos \beta) \mathbf{R}(\theta) \dot{\xi} + r \dot{\varphi} = 0. \quad (24.1)$$

Nonslip Condition.

$$(-\cos(\alpha + \beta) \sin(\alpha + \beta) d + l \sin \beta) \mathbf{R}(\theta) \dot{\xi} + d \dot{\beta} = 0. \quad (24.2)$$

In the earlier given expressions, $\mathbf{R}(\theta)$ is the orthogonal rotation matrix expressing the orientation of the robot with respect to the inertial frame, i. e.,

$$\mathbf{R}(\theta) = \begin{pmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (24.3)$$

As said before, these general expressions can be simplified for different types of conventional wheels.

For *fixed wheels*, the center of the wheel is fixed with respect to the cart and the wheel orientation is constant. This corresponds to a constant value of β and $d = 0$ (Fig. 24.2a). The nonslip equation (24.2) then reduces to

$$(\cos(\alpha + \beta) \sin(\alpha + \beta) l \sin \beta) \mathbf{R}(\theta) \dot{\xi} = 0. \quad (24.4)$$

For *steering wheels*, the center of the wheel is also fixed with respect to the cart (i. e., $d = 0$), with β time-varying, so the nonslip equation takes the form (24.2). This structure was already introduced in Fig. 24.2c.

The situation described by (24.1) and (24.2), with a nonzero-length rod AB and time-varying orientation angle β corresponds to *caster wheels*.

Swedish Wheels. The position of a Swedish wheel with respect to the cart is described, as for fixed wheels, by three constant parameters: α , β , and l . An additional parameter is required to characterize the direction, with respect to the wheel plane, of the zero component of the velocity at the contact point of the wheel. This parameter is γ , which is the angle between the axle of the rollers and the wheel plane (Fig. 24.3b).

The kinematic constraints now impose only one condition

$$[-\sin(\alpha + \beta + \gamma) \quad \cos(\alpha + \beta + \gamma) \quad l \cos(\beta + \gamma)] \\ \times \mathbf{R}(\theta) \dot{\xi} + r \cos \gamma \dot{\phi} = 0 \quad (24.5)$$

24.2.3 Robot Configuration Variables

We now consider a wheeled robot equipped with N wheels of the earlier described types. We use the following subscripts to identify quantities related to these four types: f for fixed wheels, s for steering wheels, c for caster wheels, and sw for Swedish wheels. The number of wheels of each type are denoted by N_f , N_s , N_c , and N_{sw} , with $N = N_f + N_s + N_c + N_{sw}$.

The configuration of the robot is fully described by the following generalized coordinate vector:

- *Posture coordinates*: the posture vector $\xi(t) = (x(t) \ y(t) \ \theta(t))^T$
- *Orientation coordinates*: the $N_s + N_c$ orientation angles of the steering and caster wheels, i. e., $\beta(t) = (\beta_s(t) \ \beta_c(t))^T$
- *Rotation coordinates*: the N rotation angles of the wheels, i. e., $\varphi(t) = (\varphi_f(t) \ \varphi_s(t) \ \varphi_c(t) \ \varphi_{sw}(t))^T$.

This whole set of coordinates is termed as the set of configuration coordinates. The total number of configuration coordinates is $N_f + 2N_s + 2N_c + N_{sw} + 3$.

24.2.4 Restriction on Robot Mobility

The *pure rolling conditions* for fixed, steering, and caster wheels, as well as the constraints relative to the Swedish wheels, can be written in the following compact form

$$\mathbf{J}_1(\beta_s, \beta_c) \mathbf{R}(\theta) \dot{\xi} + \mathbf{J}_2 \dot{\phi} = 0, \quad (24.6)$$

with

$$\mathbf{J}_1(\beta_s, \beta_c) = \begin{pmatrix} \mathbf{J}_{1f} \\ \mathbf{J}_{1s}(\beta_s) \\ \mathbf{J}_{1c}(\beta_c) \\ \mathbf{J}_{1sw} \end{pmatrix}.$$

In this expression, \mathbf{J}_{1f} , $\mathbf{J}_{1s}(\beta_s)$, $\mathbf{J}_{1c}(\beta_c)$, and \mathbf{J}_{1sw} are, respectively, $(N_f \times 3)$, $(N_s \times 3)$, $(N_c \times 3)$, and $(N_{sw} \times 3)$ matrices, whose forms derive directly from the kinematic constraints, while \mathbf{J}_2 is a constant $(N \times N)$ diagonal matrix whose entries are the radii of the wheels, except for the radii of the Swedish wheels which are multiplied by $\cos \gamma$.

The value $\gamma = \pi/2$ would correspond to the direction of the zero component of the velocity being orthogonal to the plane of the Swedish wheel. Such a wheel would be subject to a constraint identical to the nonslip condition for a conventional wheel; hence, losing the benefit of implementing a Swedish wheel. This implies that $\gamma \neq \frac{\pi}{2}$ and that \mathbf{J}_2 is a nonsingular matrix.

The *nonslip conditions* for caster wheels can be summarize as

$$\mathbf{C}_{1c}(\beta_c) \mathbf{R}(\theta) \dot{\xi} + \mathbf{C}_{2c} \dot{\beta}_c = 0, \quad (24.7)$$

where $\mathbf{C}_{1c}(\beta_c)$ is a $(N_c \times 3)$ matrix, whose entries derive from the nonslip constraints (24.2), while \mathbf{C}_{2c} is a constant diagonal nonsingular matrix, whose entries are equal to d .

The last constraints relate to the *nonslip conditions* for *fixed and steering wheels*. They can be summarized as

$$\mathbf{C}_1^*(\beta_s) \mathbf{R}(\theta) \dot{\xi} = 0, \quad (24.8)$$

where

$$\mathbf{C}_1^*(\beta_s) = \begin{pmatrix} \mathbf{C}_{1f} \\ \mathbf{C}_{1s}(\beta_s) \end{pmatrix},$$

where \mathbf{C}_{1f} and $\mathbf{C}_{1s}(\beta_s)$ are, respectively, $(N_f \times 3)$ and $(N_s \times 3)$ matrices.

It is important to point out that the restrictions on robot mobility result only from the conditions (24.8) involving the fixed and the steering wheels. These conditions imply that the vector $\mathbf{R}(\theta) \dot{\xi}$ belongs to $N[\mathbf{C}_1^*(\beta_s)]$, the null space of the matrix $\mathbf{C}_1^*(\beta_s)$. For any $\mathbf{R}(\theta) \dot{\xi}$ satisfying this condition, there exists a vector $\dot{\phi}$ and a vector $\dot{\beta}_c$ satisfying, respectively, conditions (24.6) and (24.7), because \mathbf{J}_2 and \mathbf{C}_{2c} are nonsingular matrices.

Obviously $\text{rank}[\mathbf{C}_1^*(\beta_s)] \leq 3$. If it is equal to 3 then $\mathbf{R}(\theta) \dot{\xi} = 0$, which means that any motion in the plane is impossible. More generally, restrictions on robot mobility are related to the rank of $\mathbf{C}_1^*(\beta_s)$, as will be discussed as follows in detail.

It is worth noticing that condition (24.8) has a direct geometrical interpretation. At each time instant the motion of the robot can be viewed as an instantaneous rotation about the instantaneous center of rotation (ICR), whose position with respect to the cart can be time varying. At each instant the velocity of any point of the cart is orthogonal to the straight line joining this point and the ICR. This is true, in particular, for the centers of the fixed and steering wheels, which are fixed points of the cart. On the other hand, the nonslip condition implies that the velocity of the wheel center is aligned with the wheel plane. These two facts imply that

the horizontal rotation axes of the fixed and steering wheels intersect at the **ICR** (Fig. 24.5). This is equivalent to the condition that $\text{rank}[\mathbf{C}_1^*(\beta_s)] \leq 3$.

24.2.5 Characterization of Robot Mobility

As said earlier, the mobility of the robot is directly related to the rank of $\mathbf{C}_1^*(\beta_s)$, which depends on the design of the robot. We define the *degree of mobility* δ_m as

$$\delta_m = 3 - \text{rank}[\mathbf{C}_1^*(\beta_s)]. \quad (24.9)$$

Let us first examine the case $\text{rank}(\mathbf{C}_{1f}) = 2$, which implies that the robot has at least two fixed wheels. If there are more than two fixed wheels, their axes intersect at the **ICR**, whose position with respect to the cart is then fixed in such a way that the only possible motion is a rotation of the cart about this fixed **ICR**. Obviously, from the user's point of view, such a design is not acceptable. We therefore assume that $\text{rank}(\mathbf{C}_{1f}) \leq 1$.

Moreover, we assume that

$$\text{rank}[\mathbf{C}_1^*(\beta_s)] = \text{rank}(\mathbf{C}_{1f}) + \text{rank}[\mathbf{C}_{1s}(\beta_s)] \leq 2.$$

These two assumptions are equivalent to the following set of conditions:

1. If the robot has more than one fixed wheel, they are all on a single common axle.
2. The centers of the steering wheels do not belong to this common axle of the fixed wheels.
3. The number $\text{rank}[\mathbf{C}_{1s}(\beta_s)]$ is equal to the number of steering wheels that can be oriented independently in order to steer the robot.

We call this number the *degree of steerability*

$$\delta_s = \text{rank}[\mathbf{C}_{1s}(\beta_s)]. \quad (24.10)$$

If a robot is equipped with more than δ_s steering wheels, the motion of the extra wheels must be coordinated in order to guarantee the existence of the **ICR** at each instant.

We conclude that, for wheeled mobile robot of practical interest, the two defined indices, δ_m and δ_s , satisfy the following conditions:

1. The degree of mobility satisfies $1 \leq \delta_m \leq 3$. The upper bound is obvious, while the lower bound means that we consider only cases where motion is possible.
2. The degree of steerability satisfies $0 \leq \delta_s \leq 2$. The upper bound can be reached only for robots without fixed wheels, while the lower bound corresponds to robots without steering wheels.
3. The following is satisfied: $2 \leq \delta_m + \delta_s \leq 3$.

Fig.24.5a,b The instantaneous center of rotation. (a) A car-like robot; (b) a three-steering-wheels robot

The case $\delta_m + \delta_s = 1$ is not acceptable because it corresponds to the rotation of the robot about a fixed **ICR**. The cases $\delta_m \geq 2$ and $\delta_s = 2$ are excluded because according to the assumptions, $\delta_s = 2$ implies $\delta_m = 1$. These conditions imply that only five structures are of practical interest, corresponding to the five pairs (δ_m, δ_s) satisfying the aforementioned inequalities, according to the following array

δ_m	3	2	2	1	1
δ_s	0	0	1	1	2

In the following, each type of structure will be designated by using a denomination of the form type (δ_m, δ_s) robot.

24.2.6 Five Classes of Wheeled Mobile Robots

We now briefly describe the five classes of wheeled robot structures, pointing out the mobility restriction inherent to each class. Details and examples can be found in Sect. 24.3 and in [24.5].

Type (3,0) Robots

These robots have no fixed and no steering wheels and are equipped only with Swedish or caster wheels. Such robots are called *omnimobile*, because they have full mobility in the plane, which means that they are able to move in any direction without any reorientation.

Type (2,0) Robots

These robots have no steering wheels, but either one or several fixed wheels with a common axle. Mobility is restricted in the sense that, at a given posture $\xi(t)$, the velocity $\dot{\xi}(t)$ is constrained to belong to a two-dimensional distribution spanned by the vector fields $\mathbf{R}^T(\theta)s_1$ and $\mathbf{R}^T(\theta)s_2$, where s_1 and s_2 are two constant vectors spanning $N(\mathbf{C}_{1f})$. A typical example of such a robot is the wheelchair.

Type (2,1) Robots

These robots have no fixed wheels and at least one steering wheel. If there is more than one steering wheel, their orientations must be coordinated in such a way that $\text{rank}[\mathbf{C}_{1s}(\boldsymbol{\beta}_s)] = \delta_s = 1$. The velocity $\dot{\boldsymbol{\xi}}(t)$ is constrained to belong to a two-dimensional distribution spanned by the vector fields $\mathbf{R}^T(\theta)s_1(\boldsymbol{\beta}_s)$ and $\mathbf{R}^T(\theta)s_2(\boldsymbol{\beta}_s)$, where $s_1(\boldsymbol{\beta}_s)$ and $s_2(\boldsymbol{\beta}_s)$ are two vectors spanning $N(\mathbf{C}_{1s}(\boldsymbol{\beta}_s))$.

Type (1,1) Robots

These robots have one or several fixed wheels on a single common axle, and also one or several steering wheels, with the conditions that their centers are not located on the common axle of the fixed wheels, and that

their orientations are coordinated. The velocity $\dot{\boldsymbol{\xi}}(t)$ is constrained to belong to a one-dimensional distribution parameterized by the orientation angle of one arbitrarily chosen steering wheel. Mobile robots built on the model of a conventional car (often called *car-like* robots) belong to this class.

Type (1,2) Robots

These robots have no fixed wheels, but at least two steering wheels. If there are more than two steering wheels, then their orientation must be coordinated in order to satisfy the condition $\text{rank}[\mathbf{C}_{1s}(\boldsymbol{\beta}_s)] = \delta_s = 2$. The velocity $\dot{\boldsymbol{\xi}}(t)$ is constrained to belong to a one-dimensional distribution parameterized by the orientation angles of two arbitrarily chosen steering wheels.

24.3 Wheeled Robot Structures

There are many design alternatives for wheeled mobile robots. Design problems of a single-body mobile robot include the selection of wheel types, the placement of wheels, and the determination of the kinematic parameters. Design objectives should be specified according to the target environments and tasks, as well as the initial and operational costs of a robot. In this section, robot structures are classified according to the number of wheels, and then features will be introduced focusing on commonly adopted designs.

24.3.1 Robots with One Wheel

A robot with a single wheel is basically unstable without dynamic control in order to maintain its balance of the body. A typical example is a unicycle. As a variation of a unicycle, a robot with a rugby-ball-shaped wheel can be used in order to improve stability in the lateral direction, as studied in [24.6].

A spherical robot can also be considered as a single-wheel robot. A balancing mechanism such as a spinning wheel is employed to achieve dynamic stability. This approach has advantages including high maneuverability and low rolling resistance. However, single-wheel robots are rarely used in practical applications, because additional balancing mechanisms are required, control is difficult, and pose estimation by pure dead reckoning is not available. An example of a spherical robot can be found in [24.7].

24.3.2 Robots with Two Wheels

In general, there are two types of two-wheel robots, as shown in Fig. 24.6. Figure 24.6a shows a bicycle-type robot. It is common to steer a front wheel and

to drive a rear wheel. Since the dynamic stability of a bicycle-type robot increases with its speed, a balancing mechanism is not necessarily required. The advantage of this approach is that the robot width can be reduced. However, a bicycle type is rarely used because it cannot maintain its pose when the robot stands still. Figure 24.6b shows an inverted-pendulum-type robot. It is a two-wheel differential drive robot.

It is possible to achieve static stability by accurately placing the center of gravity on the wheel axle. However, it is common to apply dynamic balancing control, which is similar to the conventional control problem for an inverted pendulum. The size of a robot can be re-

Fig. 24.6 (a) Bicycle-type robot and (b) inverted-pendulum-type robot

duced by using two-wheel robots, when compared with robots with more than three wheels. A typical application of a pendulum-type robot is to design a structure as a four-wheel robot, consisting of two pendulum robots connected. Then, the robot can climb stairs by lifting its front wheels while the robot reaches the stair. A major disadvantage is that control effort is always required for dynamic balancing. Examples of inverted-pendulum-type robots can be found in [24.8] and [24.9].

24.3.3 Robots with Three Wheels

Since a robot with three wheels is statically stable and has a simple structure, it is one of the most widely used structures for wheeled robots. There are a large number of designs according to the choice of individual wheel types. Every wheel introduced in Sect. 24.2.1 can be used to construct three-wheel robots. In this section, five popular design examples are described (Fig. 24.7):

1. Two-wheel differential drive
2. Synchronous drive
3. An omnimobile robot with Swedish wheels

4. An omnimobile robot with active caster wheels
5. An omnidirectional robot with steerable wheels.

Two-Wheel Differential-Drive Robot

A two-wheel differential-drive robot is one of the most popular designs and is composed of two active fixed wheels and one passive caster wheel. The robot can be classified as a type (2,0) robot in the nomenclature of Sect. 24.2.6. It is possible to extend the robot to a four-wheel robot by adding passive caster wheels. The major advantages of the robot can be summarized as follows:

- A simple mechanical structure, a simple kinematic model, and low fabrication cost.
- A zero turning radius is available. For a cylindrical robot, the obstacle-free space can easily be computed by expanding obstacle boundaries by the robot radius r .
- Systematic errors are easy to calibrate.

On the other hand, its drawbacks are:

- Difficulty of moving irregular surfaces. When the robot goes over uneven surfaces, its orientation

Fig. 24.7 (a) Two-wheel differential drive, (b) synchronous drive, (c) omnimobile robot with Swedish wheels, (d) omnimobile robot with active caster wheels, and (e) omnidirectional robot with active steerable wheels

might change abruptly if one of the active wheels loses contact with the ground.

- Only bidirectional movement is available.

Synchronous-Drive Robot

A synchronous-drive robot can be built by using centered or off-centered orientable wheels. The steering and driving motions of each wheel are mechanically coupled by chains or belts, and the motions are actuated synchronously, so the wheel orientations are always identical. The kinematic model of a synchronous drive robot is equivalent to that of the unicycle, a type (1,1) robot. Therefore, omnidirectional motion, i. e., motion in any direction can be achieved by steering the wheel orientations to the desired velocity direction. However, the orientation of the robot chassis cannot be changed. Sometimes a turret is employed to change the body orientation. The most significant advantage of the synchronous-drive robot is that omnidirectional movement can be achieved by using only two actuators. Since the mechanical structure guarantees synchronous steering and driving motions, less control effort is required for motion control. Other advantages include that odometry information is relatively accurate and driving forces are evenly distributed among all the wheels. The drawbacks of this approach can be summarized as:

- Complicated mechanical structure.
- If backlash or loose coupling is present in the chain transmission, velocity differences between wheels may occur.
- In order to achieve omnidirectional movement, the wheel orientations should be aligned to the desired velocity direction before movement, due to the non-holonomic velocity constraints.

Omnimobile Robot with Swedish Wheels

The omnimobile robot with Swedish wheels corresponds to type (3,0) in the nomenclature of Sect. 24.2.6. At least three Swedish wheels are required to build a holonomic omnidirectional robot. A major advantage of using the Swedish wheel is that omnidirectional mobile robots can be easily constructed. At least three Swedish wheels are required to build a holonomic omnidirectional robot. Since omnidirectional robots can be built without using active steering of wheel modules, the mechanical structures of actuating parts can have simple structures. However, the mechanical design of a wheel becomes slightly complicated. One drawback of the Swedish wheel is that there is a vertical vibration because of discontinuous contacts during motion. In order to solve this problem, a variety of mechanical designs have been proposed; examples can be found in [24.10] and [24.11]. Another drawback is its rela-

tively low durability when compared to conventional tires. An example of a robot using Swedish wheels can be found in [24.12].

Omnimobile Robot with Active Caster Wheels

A holonomic omnidirectional robot can be constructed by using at least two active caster wheels, and the robot also belongs to type (3,0). The robot can be controlled to generate arbitrary linear and angular velocities regardless of the wheel orientations. Since the robot uses conventional tires, the disadvantages of Swedish wheels, for example, vertical vibrations or durability problems, can be solved. An example can be found in [24.13]. The disadvantages of this robot can be summarized as follows:

- Since the location of the ground contact point (i. e., footprint) changes with respect to the robot chassis, instability can take place when the distance between the wheels is too short.
- If the robot switches its movement to the reverse direction, an abrupt change of wheel orientations may take place. This is called the shopping-cart effect, which may result in instantaneous high steering velocities.
- If a driving motor is directly attached to the wheel, wires to the motor will be wound due to steering motions. In order to avoid this, a gear train should be employed to transmit the input angular velocity from the driving motor, which is attached to the robot chassis. In this case, the mechanical structure becomes quite complicated.
- If a robot is equipped with more than two active caster wheel modules, more than four actuators are used. Since the minimum number of actuator to achieve holonomic omnidirectional motion is three, this is an overactuated system. Therefore, actuators should be accurately controlled in a synchronous way.

Omnidirectional Robot with Active Steerable Wheels

Centered orientable wheels are also employed to build omnidirectional robots; at least two modules are required. A significant difference between the active caster wheel and the centered orientable wheel is that the wheel orientation should always be aligned with the desired direction of velocity direction, as computed by inverse kinematics. This fact implies that this robot is nonholonomic and omnidirectional: it is a type (1,2) robot. The control problem is addressed in [24.14]. The mechanical drawbacks are similar to those of using active caster wheels (i. e., many actuators and compli-

cated mechanical structures). Since the driving motor is directly attached to the driving axis in many cases, allowable steering angles are limited in order to prevent wiring problems.

There are a lot of design candidates for three-wheel robots, other than the five designs described earlier. They can be classified and analyzed according to the scheme presented in Sect. 24.1. The aforementioned designs can be extended to four-wheel robots to improve stability. Additional wheels can be passive wheels without adding additional kinematic constraints. Active wheels can also be added and should be controlled by solving the inverse kinematics problem. Four-wheeled robots require suspension to maintain contact with the ground to prevent wheels from floating on irregular surfaces.

24.3.4 Robots with Four Wheels

Among the various four-wheel robots, we focus on the car-like structure. The car-like structure has been called as the Ackermann steering geometry that was shown in Fig. 24.3c. The front two wheels should be synchronously steered to keep the same instantaneous center of rotation. It is clear that the orientations of two front wheels are slightly different because the curvatures of rotation are different. As a result, this solution is kinematically equivalent to a single orientable wheel and the robot can be classified as a type (1,1) robot. A major advantage of a car-like robot is that it is stable during high-speed motion. However, it requires a slightly complicated steering mechanism. If the rear wheels are actuated, a differential gear is required to obtain pure rolling of the rear wheels during the turning motion. If the steering angle of the front wheel cannot reach 90° , the turning radius becomes nonzero. Therefore, parking motion control in a cluttered environment becomes difficult.

24.3.5 Special Applications of Wheeled Robots

Articulated Robots

A robot can be extended to an articulated robot, which is composed of a robot and trailers. A typical example is the luggage-transporting trailer system at airports. By exploiting trailers, a mobile robot obtains various practical advantages. For example, modular and reconfigurable robots can change their configuration according to service tasks. A common design is a car with multiple passive trailers, which is the simplest design of an articulated robot.  VIDEO 326 shows another example of a trailer robot. From the viewpoint of control, some significant issues have been made clear, including

Fig. 24.8 An active trailer system (after [24.16])

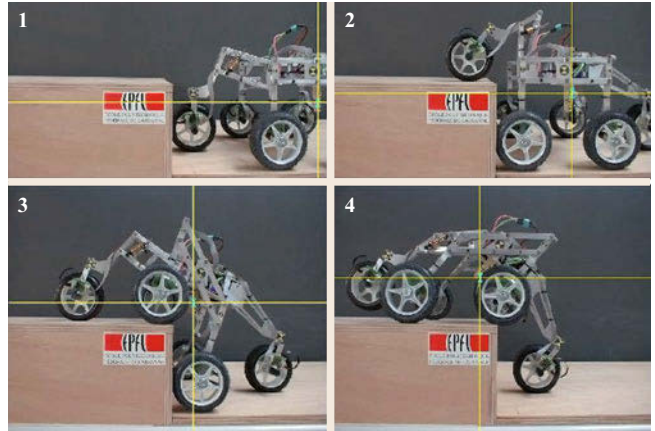

Fig. 24.9 A mobile robot for rough terrain (after [24.17])

a proof of controllability and the development of open- and closed-loop controllers using canonical forms such as the chained form. The design issues for trailer systems are the selection of wheel types and decisions regarding the link parameters. In practical applications, it is advantageous if trailers can move along the path of the towing robot. Passive trailers can follow the path of a towing robot within a small error by using a special design of passive steering mechanism for trailers; see, for example, [24.15].

On the other hand, active trailers can be used. There are two types of active trailers. A first approach is to actuate wheels of trailers. The connecting joints are passive, and two-wheel differential-drive robots can be used as active trailers. By using this type of active trailers, accurate path-following control can be achieved. The second approach is to actuate connecting joints. The wheels of the trailer are passively driven. By appropriate actuation of the connecting joints, the robot can move without wheel actuation, by snake-like motions. As an alternative design, we can use an active prismatic joint to connect trailers, in order to lift the neighboring trailer. By allowing vertical motion, a trailer system can climb stairs and traverse rough terrain. Examples of active trailers can be found in [24.16].

Hybrid Robots

A fundamental difficulty of using wheels is that they can only be used on flat surfaces. To overcome this problem, wheels are often attached to a special link mechanism. Each wheel is equipped with independent actuators and a linkage mechanism enables the robot to adapt its configuration to irregular ground conditions (VIDEO 329). A typical design can be found in [24.17] and can be understood as a hybrid robot

that is a combination of a legged robot and a wheeled robot. Another hybrid example is a robot equipped with both tracks and wheels. Wheels and tracks have complementary advantages and disadvantages. Wheeled robots are energy efficient; however, tracked robots can traverse rough terrain. Therefore, a hybrid robot can selectively choose its driving mechanism according to environmental conditions, although fabrication cost increases.

24.4 Wheel–Terrain Interaction Models

A wheeled robot's mobility properties are governed by forces generated at the wheel–terrain contact interface. The ability to accurately model wheel–terrain interaction forces is therefore an important aspect of robot design, simulation, and control. These forces are strongly influenced by the relative stiffness of the wheel and terrain. Generally, there are four possible wheel–terrain interaction cases. The first case is that of a rigid wheel traveling on rigid terrain (Fig. 24.10a). The second case is that of a rigid wheel traveling on deformable terrain (Fig. 24.10b). The third case is that of a deformable wheel traveling on deformable terrain (Fig. 24.10c). The fourth case is that of a deformable wheel traveling on rigid terrain (Fig. 24.10d). Models for these four cases are presented as follows. It should be noted that while many different types of models (i.e., finite element, discrete element, empirical) have been developed for each of these four cases, the focus here is on analytical models that are broadly suitable for analysis, simulation, design, and control purposes.

24.4.1 Rigid Wheels on Rigid Terrain

Many robots employ wheels made of metal, stiff rubber, or other materials that deform very little when subject to loading experienced during operation. When operated on stiff surfaces such as indoor flooring, pavement, or stone, wheel–terrain interaction can be reasonably approximated as a point contact. An interaction model based on classical Coulomb friction can then be employed to describe bounds on available tractive forces, F_x , and lateral forces, F_y , as a function of the load on the wheel, W , for a robot with n wheels traveling on a surface with coefficient of friction μ

$$F_{xi} \leq \mu_x W_i, \quad i = 1 \dots n, \quad (24.11)$$

$$F_{yi} \leq \mu_y W_i, \quad i = 1 \dots n. \quad (24.12)$$

Since the frictional force can be generated in any direction, and its magnitude is limited, a bound on the norm of the frictional and lateral forces can be ex-

pressed as

$$\left(\frac{F_{xi}}{\mu_x W_i} \right)^2 + \left(\frac{F_{yi}}{\mu_y W_i} \right)^2 = 1, \quad i = 1 \dots n. \quad (24.13)$$

Equation (24.13) represents a concept known as the friction ellipse (Fig. 24.11). When the effective friction is equal in all directions the ellipse becomes a circle.

24.4.2 Rigid Wheels on Deformable Terrain

Robotic locomotion in outdoor, off-road terrain frequently results in deformation of the terrain, especially when the terrain is composed of a deformable material such as sand, silt, loam, or clay. When the wheel is constructed of a rigid material such as metal or stiff rubber, or the tire inflation pressure is high enough such that tire deformation is small, wheel–terrain interaction occurs along an arc of the wheel, rather than at a single point (Fig. 24.10b). In such scenarios, the Coulomb friction model described in Sect. 24.4.1 does not accurately represent the relationship between the wheel load

Fig. 24.10a–d Four cases of wheel–terrain interaction mechanics: (a) rigid wheel traveling over rigid terrain, (b) rigid wheel traveling over deformable terrain, (c) deformable wheel traveling over deformable terrain, and (d) deformable wheel traveling over rigid terrain

Fig. 24.11 Illustration of friction ellipse concept to represent constraint on longitudinal and lateral friction

and tractive forces. This is because the mechanism for force generation derives primarily from shearing along failure planes in the terrain, rather than from frictional contact at a point on the wheel–terrain interface.

Models of the interaction of rigid wheels on deformable surfaces were developed by *Bekker* in the 1950s and 1960s in the context of large military vehicles [24.18]. Bekker’s research gave rise to the discipline of *terramechanics*, i.e., the study of vehicle–terrain interaction phenomena. Bekker’s terramechanics models have subsequently been applied to robotic systems at a range of sizes [24.19] and [24.20]. However, Bekker performed his original analyses in the context of large military vehicles, which were typically several meters in length and with gross vehicle weights exceeding 500 kg. The accuracy of such models when used to analyze the performance of small robotic systems remains an open research question [24.21] and [24.22].

A description of terramechanics models for the case of rigid wheels on deformable surfaces is presented in Chap. 55, in the context of Space Robotics. However, Chap. 55 assumes that the wheel is constructed of a rigid material such as metal, which is typical for planetary exploration rovers but rare for robots operating on Earth. As noted earlier, a pneumatic tire will behave as a rigid wheel if the average tire ground pressure, which is a function of the tire carcass stiffness and inflation pressure, exceeds some critical ground pressure. The average tire ground pressure can be obtained experimentally by measuring the tire contact patch area while the tire is subjected to a series of known vertical loads and inflation pressures. The critical ground pressure is defined as

$$p_{\text{gr}} = \left(\frac{k_c}{b} + k_\phi \right)^{\frac{1}{(2n+1)}} \left(\frac{3W}{(3-n)b_{\text{ti}}\sqrt{D}} \right)^{\frac{2n}{2n+1}}, \quad (24.14)$$

where k_c , k_ϕ , n are the soil-dependent parameters, b is the smallest dimension of the (typically rectangular) wheel–terrain contact patch, b_{ti} is the tire width, W is the vertical load on the tire, and D is the tire diameter.

If the average tire ground pressure exceeds the critical ground pressure, a pneumatic tire can be modeled as a rigid wheel interacting with a deformable surface. This scenario is governed by the equations presented in Chap. 55. If the average tire ground pressure does not exceed the critical ground pressure, a pneumatic tire can be modeled either as a deformable wheel interacting with deformable terrain, or as a deformable wheel interacting with rigid terrain. Models of these scenarios are presented in Sects. 24.4.3 and 24.4.4.

24.4.3 Deformable Tires on Deformable Terrain

When the average tire ground pressure does not exceed the critical ground pressure, both the tire and the terrain surface may undergo deformation. Accurate modeling of this interaction thus requires consideration of phenomena related to both soil deformation (most notably, soil compaction, and shear deformation) and tire deformation. Several semiempirical models for this scenario, based on Bekker theory, have been developed in recent years.

A simple approach to modeling in this interaction scenario was initially proposed by Bekker, and further developed by *Harnisch* [24.23]. This approach relies on the observation that tire deformation serves to increase the size of the wheel–terrain contact patch, and thus reduce the average ground pressure and minimize sinkage. Bekker proposed the *substitute circle* concept, which embodies the notion that the deformable tire can be equivalently represented by a rigid tire of increased diameter, to yield identical sinkage (Fig. 24.12). The diameter of the larger rigid tire can be computed via the following method:

1. Assuming zero slip, sinkage for the original tire diameter D , assumed to be rigid, is calculated for the vertical load W and soil parameters.
2. Knowing the tire load-deflection characteristics, for the given inflation pressure the tire deflection δ can be calculated.
3. The diameter of the larger substitute circle D' will correspond to the diameter of the circle that passes through P_1 , P_2 , and P_3 .

Once the outer circle diameter is known, all other quantities will be calculated following the standard methodology presented in Chap. 55, substituting D' for the original wheel diameter D .

Fig. 24.12 Illustration of substitute circle concept

An alternative approach, based on a more physically realistic model of the deformed tire geometry, was proposed by Wong [24.24]. Here, the tire geometry is represented as a circular arc with a perfectly flat (i.e., horizontal) base (Fig. 24.13). The pressure distribution under the flat section BC is assumed to be uniform, and equal to the average ground pressure of the tire p_g . Disregarding shear effects and soil elastic rebound (section CD), it is possible to calculate the tire deflection δ by balancing vertical forces

$$W = bp_g l_t + W_{AB}, \quad (24.15)$$

where b is the tire width, l_t is the length of the flat section BC, and W_{AB} is the vertical reaction exerted by the soil along the undeformed tire section AB

$$W_{AB} = \left[b \left(\frac{k}{l} + k_\phi \right) \sqrt{D} (z_0 + \delta)^{n-1} \right] \frac{(3-n)(z_0 + \delta)^{\frac{3}{2}} - (3-n)\delta^{\frac{3}{2}} - 3z_0\sqrt{\delta}}{3}, \quad (24.16)$$

Fig. 24.13 Diagram of deformable wheel traveling over deformable terrain

where D is the undeformed tire diameter and z_0 is the static sinkage that can be calculated through standard pressure–sinkage relations

$$z_0 = \begin{cases} \left(\frac{p_g}{(k_c/l_t) + k_\phi} \right)^{\frac{1}{n}} & (l_t < b) \\ \left(\frac{p_g}{(k_c/b) + k_\phi} \right)^{\frac{1}{n}} & (l_t \geq b) \end{cases}, \quad (24.17)$$

where $l_t = 2\sqrt{D\delta - \delta^2}$ is the contact patch length. Although not strictly correct, the tire ground pressure p_g can be approximated by the tire inflation pressure, a known variable. Following this assumption, it is possible to solve (24.16) for the tire deflection δ .

Once the deformed tire shape has been calculated, all other relevant quantities (i.e., sinkage, drawbar force, and torque) can be calculated. Since the tire profile is nonsmooth, the normal and tangential stresses are described by piecewise expressions. The vertical load balance can be written as

$$W = br \int_{\theta_r}^{\theta_c} (\sigma \cos \theta - \tau \sin \theta) d\theta + b D p_g \sin \theta_c + br \int_{\theta_c}^{\theta_f} (\sigma \cos \theta + \tau \sin \theta) d\theta. \quad (24.18)$$

The aforementioned equation can be solved for the entry angle θ_r . The angle θ_c can be derived from the tire deflected shape. Once the tire–terrain geometry is determined, the sinkage can be found. Note that this new sinkage will differ from the static sinkage z_0 . It is then possible to calculate drawbar pull F_x and driving torque

$$F_x = br \int_{\theta_r}^{\theta_c} (\sigma \cos \theta + \tau \sin \theta) d\theta + b \int_0^{l_t} \tau dx + br \int_{\theta_c}^{\theta_f} (-\sigma \cos \theta + \tau \sin \theta) d\theta, \quad (24.19)$$

$$T = br^2 \int_{\theta_r}^{\theta_c} \tau d\theta + br \cos \theta_c \int_0^{l_t} \tau dx + br^2 \int_{\theta_c}^{\theta_f} \tau d\theta. \quad (24.20)$$

Another flexible tire model developed by *Senatore* and *Sandu* is similar to the approach proposed by Wong, however it calculates the tire deflection as a function of inflation pressure, and also models multi-pass effects [24.25]. Generally speaking, all of the flexible tire models proposed to date have various advantages and drawbacks, and none have gained universal approval in the research community.

24.4.4 Deformable Tires on Rigid Terrain

In scenarios where the tire stiffness is significantly lower than the terrain stiffness, only the tire will experience significant deformation. This scenario has been studied extensively in the automotive community, since it is the typical interaction scenario for passenger and commercial vehicles operating on paved roads. Here, two common models of steady-state tire–terrain interaction are briefly described: the brush model and the magic formula model [24.26].

The brush model models the tire contact patch as a row of elastic bristles in contact with the ground. Carcass, belt, and tread element compliance is captured by a lumped bristle compliance. For the case of pure longitudinal slip, the tractive force can be calculated as

$$F_x = 2c_{px}\alpha^2 \frac{V_{sx}}{V_x}, \quad (24.21)$$

where c_{px} is the longitudinal tread element stiffness per unit length and other quantities are illustrated in Fig. 24.14.

In a similar manner, the lateral force can be calculated as follows

$$F_y = 2c_{py}\alpha^2, \quad (24.22)$$

where α is the slip angle. As previously discussed for the case of rigid wheels on rigid terrain, combined slip operation will limit the availability of longitudinal and lateral thrust [24.26].

The magic formula model is an empirical model that has found widespread application due to its flexibility and reduced computational burden. The model is based on a combination of trigonometric functions that generate a curve that (usually) passes through the origin, reaches a peak value, and then tends to a horizontal asymptote: this behavior is typical of force/moment versus slip characteristics of modern tires, regardless of tire size, construction, inflation pressure, and other characteristics. The general form of the magic formula model is

$$y = D \sin\{C \arctan[Bx - E(Bx - \arctan Bx)]\}, \quad (24.23)$$

Fig. 24.14 Brush tire model for analyzing interaction of deformable tire and rigid terrain

Fig. 24.15 Diagram illustrating influence of parameters of magic tire model

with $Y(X) = y(x) + S_V$ and $x = X + S_H$. Here, Y represents the output variable, which may be F_x , F_y , or M_z , and X represents the input variable, which may be $\tan \alpha$ or k (i. e., the lateral or longitudinal slip). The relation also contains several empirically determined values, as follows: B represents a stiffness factor; C a shape factor; D a peak value; E a curvature factor; S_H a horizontal shift; and S_V a vertical shift. These factors are illustrated in Fig. 24.15.

24.5 Wheeled Robot Suspensions

A suspension is a system of linkages, springs, dampers, and actuators that govern the relative motion between a robot's wheels and body. These mechanisms include a degree of freedom allowing the wheel to spin, and optional degrees of freedom for steering and vertical translation. Suspension mechanisms are useful when driving

over uneven surfaces for several reasons. First, a suspension allows the wheels to maintain contact with the ground despite disturbances from the uneven ground surface, which allows generation of traction, braking, and cornering forces. Additionally, suspensions provide load-bearing and dissipative elements (i. e., springs,

dampers, and active or semiactive actuators) to mitigate the effect of disturbances on robot body motion, and thus allow for improved obstacle negotiation and sensor or payload stabilization. Key issues in suspension design include the design of suspension linkage kinematics and selection of load-bearing and dissipative elements.

Suspension linkage kinematics are designed to allow vertical displacement of the wheels. Typical suspension mechanisms include simple prismatic joints, rotational joints with a wheel attached to a trailing arm, and 4-bar linkages. For car-like wheeled robots, substantial inspiration can be drawn from the design of passenger vehicle suspensions, which has received vast research attention [24.27]. A comprehensive treatment of the design of suspension linkage kinematics is beyond the scope of this chapter. Interested readers are referred to [24.28].

The selection of load-bearing and dissipative elements is typically based on analysis of low-order models of the suspension subject to expected operational conditions. Common methods for modeling passive and semiactive suspensions are presented in the following. Analysis of these models allows for principled selection of springs, dampers, and active or semiactive actuators that form the basis of nearly all wheeled robot suspensions.

24.5.1 Passive Suspension Dynamics

Arguably the most common passive suspension design consists of a parallel spring and damper mounted between the robot body and wheels. A simple model for analyzing the vertical dynamics of this suspension is commonly referred to as the quarter car model [24.29] and is illustrated in Fig. 24.16. The fraction of body mass supported by the suspension element, m_b , is connected to a wheel with mass m_w by a spring element with stiffness k_s and a damping element with damping

Fig.24.16a,b Quarter car model for passive suspension modelling (a) and quarter car model with ideal sky-hook semi-active suspension control (b)

coefficient b_s . The wheel stiffness is denoted by k_w , and transmits vertical excitation from the uneven terrain surface. The heights of the body mass, wheel mass, and terrain surface are given by z_b , z_w , and z_u , respectively.

A state vector x for this model is composed of the suspension displacement $d_s = z_b - z_w$, wheel spring displacement $d_w = z_w - z_u$, and velocities \dot{z}_b , \dot{z}_w , as shown in (24.24), along with a linear state space model (24.25)–(24.27). Note that the input to the model is the vertical terrain velocity \dot{z}_u . This is a convenient formulation for linear systems analysis since \dot{z}_u can be modeled as white noise with intensity proportional to the vehicle's forward speed and a road roughness parameter [24.29].

$$x = \begin{pmatrix} d_s \\ d_w \\ \dot{z}_b \\ \dot{z}_w \end{pmatrix} \quad (24.24)$$

$$\dot{x} = Ax + Bu \quad (24.25)$$

$$A = \begin{pmatrix} 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 1 \\ -k_s/m_b & 0 & -b_s/m_b & b_s/m_b \\ k_s/m_w & -k_w/m_w & b_s/m_w & -b_s/m_w \end{pmatrix} \quad (24.26)$$

$$B = \begin{pmatrix} 0 \\ -1 \\ 0 \\ 0 \end{pmatrix}. \quad (24.27)$$

To investigate the properties of this model, transfer functions $G(s) = Y(s)/U(s)$ are computed for outputs of interest $y = Cx$ as

$$G(s) = C(sI - A)^{-1}B. \quad (24.28)$$

With a white noise input, all frequencies are equally represented. Thus, the magnitude of the transfer function $|G(j\omega)|$ at a given frequency ω represents the frequency response of each output. Two outputs are of particular interest for suspension design purposes: the wheel displacement d_w and body acceleration \ddot{z}_b . This is because the wheel displacement corresponds to variations in the wheel contact force, and thus informs the road holding and maneuvering capability of the robot. The body acceleration represents the amount of vibration experienced by the sensors and payloads mounted on the robot body.

The output matrix for the wheel displacement d_w is

$$C = (0 \quad 1 \quad 0 \quad 0), \quad (24.29)$$

and the output matrix for the body acceleration \ddot{z}_b is

$$C = \left(-\frac{k_s}{m_b} \quad 0 \quad -\frac{b_s}{m_b} \quad \frac{b_s}{m_b} \right). \quad (24.30)$$

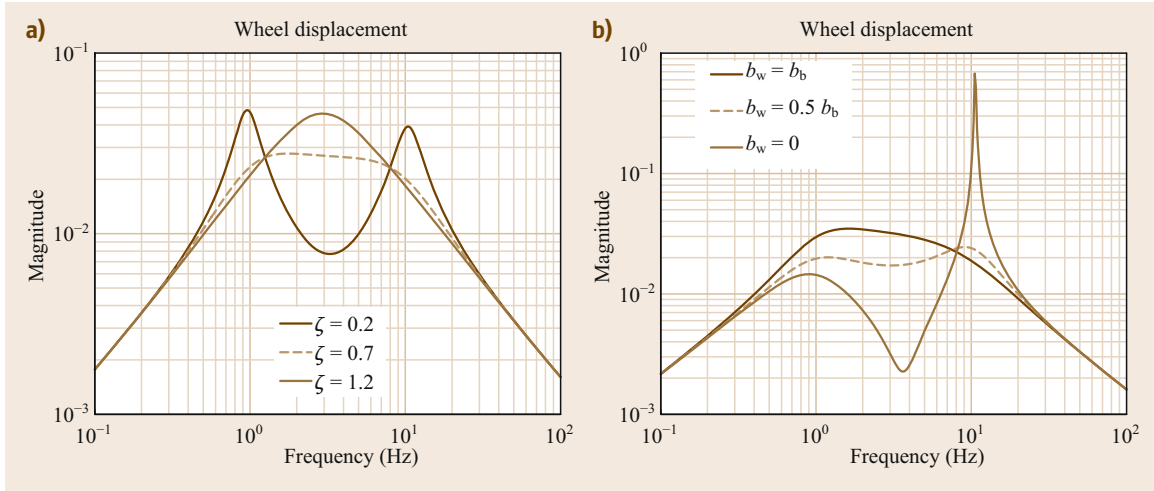

Fig.24.17a,b Wheel displacement frequency response for passive suspension (a) and semiactive suspension. Wheel displacement frequency corresponds to wheel contact force variation and road holding capability

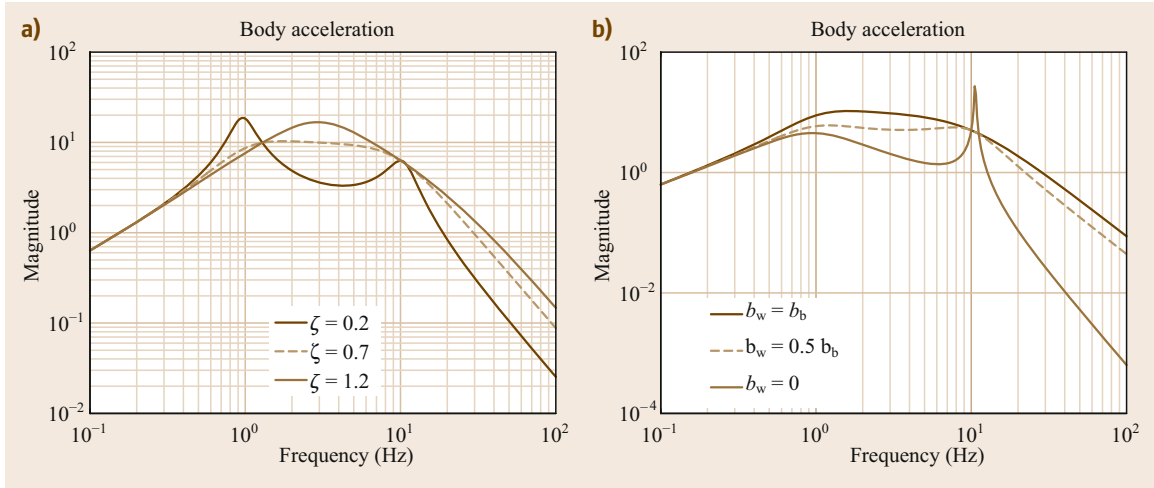

Fig.24.18a,b Body acceleration frequency response for passive suspension (a) and semiactive suspension (b). Body acceleration frequency corresponds to the vibration of sensors and payloads mounted on the robot body

The frequency response of wheel displacement and body acceleration are shown in Figs 24.17 and 24.18, respectively. These plots are shown with the following representative parameter values for a passenger vehicle: the ride frequency $\omega_b = \sqrt{k_s/m_b} = 2 \pi \text{ rad/s}$, the wheel hop frequency $\omega_w = \sqrt{k_w/m_w} = 20 \pi \text{ rad/s}$, the mass ratio $\rho = m_w/m_b = 0.1$, and the damping ratio $\zeta = b_s/(2\sqrt{k_s m_b}) = (0.2, 0.7, 1.2)$. Various damping ratios are shown to illustrate the behavior of underdamped, critically damped, and over-damped suspensions.

For the underdamped case, where $\zeta = 0.2$, resonant peaks (which are generally undesirable) exist in

the frequency response near ω_b and ω_w for both the wheel displacement and body acceleration. For the over-damped case, where $\zeta = 1.2$, the peak response occurs between the resonant peaks. For the (approximately) critically damped case, where $\zeta = 0.7$, the peak responses are reduced, and for this reason many suspension are designed to exhibit critical damping.

24.5.2 Semiactive Suspension Dynamics

The introduction of controllable actuators to the suspension allows for shaping of the system's dynamic response, and can improve road holding performance

and reduce body vibration. Suspension systems integrated with controllable actuators are referred to as active or semiactive suspensions. Active suspensions refer to systems with powered rotational or linear actuators capable of both supplying and absorbing significant amounts of energy, such that the actuator effectively replaces the passive components in a traditional suspension. Such systems are rare due to their complexity and cost. A simpler and more inexpensive (and therefore more common) approach to controllable suspensions is to employ semiactive elements. This refers to elements that can absorb energy in a controlled manner, such as active (e.g., magnetorheological) fluid dampers. Semiactive suspensions can be modeled in a manner similar to passive suspensions with a time-varying, positive damping coefficient $b_s(t) \geq 0$.

Semiactive suspension control schemes attempt to control the damping coefficient $b_s(t)$ to emulate dampers with coefficients b, b acting on the absolute velocities of the body and wheels, in order to reduce the effect of wheel vibration on the robot body. A common technique known as a sky-hook controller is illustrated in Fig. 24.16. The technique can be approximated by applying the damper force F given in the following. Note that a semiactive system can only approximate this control, as F is constrained as $F(\dot{z} - \dot{z}) \leq 0$.

$$F = -b\dot{z} + b\dot{z} \quad (24.31)$$

To illustrate the potential improvement achievable by the use of a semiactive suspension with a sky-hook controller, frequency responses of the semiactive suspension quarter car model with F given earlier are plotted in Figs 24.17 and 24.18. The model parameters are identical to the values from the previous section for critical damping $\zeta = 0.7$, with damping coefficients $b = b$ and $b = (b, 0.5b, 0)$. Note that the case $b = b$ is identical to the passive, critically damped case.

With no wheel damping, $b = 0$, both frequency responses are improved for $\omega \ll \omega$, and the body acceleration response is improved for $\omega \gg \omega$. Near ω , however, there exist substantial resonant peaks for both outputs. With moderate wheel damping $b = 0.5b$, the amplitude of the resonant peaks near ω are reduced and both peak responses are reduced, though performance improvements of $b = 0$ are not matched for frequencies far from ω .

While the sky-hook and other suspension control algorithms can improve the dynamic response of the vehicle, it is important to note some inherent trade-offs in semiactive and active suspension control. It has been proven that road holding and attenuation of body vibration can be concurrently improved through active control for frequencies below the wheel hop frequency, ω [24.29]. At frequencies above ω , however, any attempts to improve one of these quantities necessarily causes the other to degrade.

24.6 Conclusions

Wheels are the most commonly employed running gear for mobile robots due to their relative simplicity, robustness, and low cost. The number of possible wheeled mobile robot realizations is almost infinite, depending on the number, type, implementation, geometric characteristics, and motorization of the wheels. This chapter has described several such realizations. Notwithstanding this variety, it is possible to classify WMRs into only five generic categories. This categorization aids understanding of wheel structures through simplification. Practical robot structures have been classified according to the number and type of wheels. Wheel-terrain interaction models have been presented to allow the analysis of tractive force generation capability, for design and simulation purposes. Finally, a brief description of common suspension systems has been presented, including a presentation of structures and dynamic models.

Covering about two-thirds of the earth, the ocean is an enormous system that dominates processes on the Earth and has abundant living and non-living resources, such as fish and subsea gas and oil. Therefore, it has a great effect on our lives on land, and the importance of the ocean for the future existence of all human beings cannot be overemphasized. However, we have not been able to explore the full depths of the ocean and do not fully understand the complex processes of the ocean. Having said that, underwater robots including remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs) have received much attention since they can be an effective tool to explore the ocean and efficiently utilize the ocean resources. This chapter focuses on design issues of underwater robots including major subsystems such as mechanical systems, power sources, actuators and sensors, computers and communications, software architecture, and manipulators while Chap. 51 covers modeling and control of underwater robots.

25.1 Background 595

25.1 Background

The ocean covers about two-thirds of the earth and has a great effect on the future existence of all human beings. Underwater robots or unmanned underwater vehicles (UUVs) can help us better understand marine and other environmental issues, protect the ocean resources of the earth from pollution, and efficiently utilize them for human welfare.

Most UUVs commercially available in the market are tethered and remotely operated, referred to as remotely operated vehicles (ROVs). The operators on the mother vessel control the ROV by sending control

signals and power to the vehicle and receiving video, status, and other sensory data via an umbilical cable. Most work-class ROVs are equipped with one or multiple video cameras and lights, sonars, a still camera, one manipulator, one grabber, and a wide range of sampling devices. The large deep-sea ROVs use a tether management system (TMS) that allows the vehicle to be deployed using a strong but heavy umbilical cable and then flown out from the TMS using a lighter, more flexible cable. ROVs must have high bandwidth for high-resolution video and data transmission.

The US Navy funded the early **ROV** technology development in the 1960s. They were used to recover underwater ordnance. **ROVs** have been used for various applications including military operations, environmental systems, scientific missions, ocean mining, and gas and oil industry [25.1]. Visiongain analysis indicates that total spending on **ROVs** in the energy industry will reach about \$2.7 billion in 2022 as **ROVs** are required for more inspection, maintenance, drill support, and decommissioning activities than ever before.

However, since most commercial **ROV** systems currently have some operational issues such as very high operational costs with mother vessels and operator fatigue, the demand for advanced underwater robot

technologies that would lead to next generation work-class **ROV** systems or autonomous underwater vehicles (**AUVs**) has been growing. A survey paper on **AUVs** was published by Yuh [25.2] in 2000. The paper describes key areas, such as dynamics, control systems, navigation, sensors, communications, power systems, pressure hulls, fairing, and mechanical manipulators. It also presents existing **AUV** systems and components commercially available in the market then.

This chapter focuses on design issues with each major subsystem of underwater robots, such as mechanical systems, power sources, actuators and sensors, computers and communications, software architecture, and manipulators.

25.2 Mechanical Systems

Every 10 m adds approximately 1 atm of water pressure on a robot body and the chemical environment of the seawater is highly corrosive. Therefore, mechanical systems that have excellent structural strength, and excellent chemical and environmental resistance are needed.

An underwater robot's mechanical structure can be divided into three functional subsystems: frame, pressure vessel, and fairing. Frame is the primary skeleton of the robot. It defines the robot's shape, supports its weight both in and out of the water, provides mechanical support, resists hydrodynamic forces of motion and additional force due to operation of tools, and protects against any damages [25.3]. Its design must be based on structural analysis. A pressure vessel should be a waterproof structure and it must be strong enough to withstand water pressure at a target design depth. Typically, a cylindrical or spherical shape is the most effective way to maximize strength at the expense of low space efficiency. A pressure vessel with a larger diameter would result in increased cost of materials and machining since it requires increasing the thickness of the pressure vessel for the same strength. Consequently, the pressure vessel would become heavier. Therefore, selecting appropriate materials for a pressure vessel is very important. Fairing is like a skin of the robot. A fairing that covers all or parts of an underwater robot offers some advantages, such as an aesthetically pleasing exterior, a decreased drag force, and protection.

25.2.1 Frames and Pressure Hulls

The frame must be designed considering the following operational conditions:

1. On the ground without motion
2. Underwater in motion
3. Hanging from a crane for launch and recovery.

The major points of acting force for each condition are totally different. The static gravitational force is enough to be considered for the first case. For the second case, we should consider buoyancy force, gravitational force as well as all thruster forces in a dynamic state. During the launch and recovery stages, the enormous snap force, due to the mother ship's vertical motion can be concentrated on a lifting point of the robot.

The structural design and analysis must be conducted to take advantages of shapes offering high strength and stiffness for their weight. At the same time, materials should be chosen to give the maximum structural performance with the minimum weight [25.4]. An important point is that weights in both air and water must be carefully calculated. One should note that buoyancy materials will also increase the overall weight of the robot in air. A factor of safety is one of crucial parameters in designing mechanical systems. Incorporating a factor of safety may result in 50% overdesign for a manned system and 10% overdesign for an unmanned system [25.5]. Figure 25.1 shows a deep-sea **ROV**, HEMIRE's open frame that is made of aluminum. HEMIRE was developed by Korea Research Institute of Ships and Ocean Engineering (**KRISO**) ( VIDEO 796). On the other hand, a closed frame or a fairing is desirable for **AUVs**, due to limited on-board power sources for required hydrodynamic performance.

The first and ultimate goal in designing a pressure vessel is to provide a watertight environment, where on-board computers, sensors, or normal batteries are installed. Therefore, two important design factors are wa-

terproof sealing design and water pressure-resistant design. When given specifications, such as an inside diameter (ID) or an outer diameter (OD), length, thickness, and materials, we must analyze buckling stress and yield stress. They are the dominant factors for the deep-sea (high pressure) environment [25.6]. A spherical- or cylindrical-shaped pressure vessel would be good to withstand the hydrostatic pressure; however, a pressure vessel of cylindrical shape is considered a better alternative as it provides a better placement for the components. Hydrodynamic design would not be needed for pressure vessels placed inside a frame with fairing. However, if the body of an underwater robot is designed as a pressure vessel, hydrodynamics in designing a pressure vessel must be considered to reduce the drag, cavitation, and acoustic noise [25.7].

Frames and pressure vessels must have the structural analysis using the finite element method (FEM) software, and nondestructive tests and/or pressure testing to avoid any mechanical defects. Pressure testing is the best way to reveal hidden defects in materials and in machining process even though it requires additional time, cost and nontrivial facilities. It is a critical environmental test because a hydrostatic pressure test, cyclic pressure test for fatigue test due to repeated deployments, and failure mode test to compare a designed crush depth with its real depth are all involved [25.5]. Pressure testing facilities provide not only a chamber for external pressure testing but also various types of measurement sensors and systems to record any changes during the testing.

25.2.2 Materials and Buoyancy

Besides high strength and high stiffness, one should consider good corrosion resistance and machinability

Fig. 25.1 Aluminum frame of an ROV, Hamire, developed by KRISO, Korea

in choosing materials for frames and pressure vessels [25.7].

A typical underwater robot for shallow water tends to use aluminum, polycarbonate (PC), and polyoxymethylene (POM), while high strength steel, titanium, and composites are considered for a deep-sea underwater robot. The hybrid ROV, *Nereus*, is for a depth of 11 000 m and employs two pressure vessels composed of 96% alumina ceramic because its high compressive strength-to-weight ratio allows for near neutrally buoyant pressure vessels capable of going to these extreme depths [25.8]. Basic properties of materials are described later.

Steel is commonly used because of its high tensile strength and low cost. For marine applications, surface treatment of steel must be done because it is susceptible to corrosion or rusting. It tends to distort magnetic fields. Type 316 stainless steel is usually regarded as the standard marine grade and it is typically used for hydraulic, pneumatic and fasteners, but it is difficult to machine and weld. The aluminum alloy is lightweight and has high strength. It is of reasonable value and not related to magnetic effects. Since it is vulnerable to corrosion, surface treatment is also required. High heat conductivity is another advantage for a pressure vessel of aluminum alloy. The titanium alloy has a very high strength-to-weight ratio, excellent corrosion resistance without any surface treatment, low electric conductivity, and no magnetic field distortion. Drawbacks include low heat conductance, difficulties in machining and welding, and high cost.

The most commonly used composite for marine applications is glass-fiber reinforced plastic (GFRP), which has a very high strength-to-weight ratio, excellent corrosion resistance, and a competitive price tag. Carbon fiber reinforced plastic (CFRP) performs better, but it is more expensive. For deep-sea applications, CFRP would bring lots of advantages. The pressure vessel of the Seaglider for 6000 m was made of CFRP because of its ability to achieve weight to displacement ratios of less than 0.5 [25.9]. However, it has not been popular in the market mainly because of difficulties in machining. Metal matrix composites (MMC) and ceramic alloy have many advantages over other materials. In particular, they have high elastic modulus and hardness, high melting points, low thermal expansion, and good chemical resistance.

Instead of metals and composite materials, acrylic (plexiglas), POM (polyoxymethylene, acetal, delrin), PC (polycarbonate lexan), ABS (acrylonitrile-butadiene-styrene), PVC (polyvinyl chloride), and plastic are alternatives for underwater robots operating in shallow-water environments. The main advantages of the abovementioned materials are excellent

Table 25.1 Properties of materials for an underwater robot

Specification	Density (kg/dm ³) (typical)	Tensile strength (MPa), Ultimate (typical)/Yield (typical)	Modulus of elasticity (GPa) (typical)
Steel (HY80)	7.87	482–689/276–517	190–210 (200)
Stainless steel (Type316)	7.75–8.1	620–560/415–290	193
Aluminum 6061-T6	2.7	310/276	68.9
Aluminum 7075-T6	2.81	572/503	71.7
Titanium Ti-6Al-4V	4.43	950/880	113.8
GFRP, E-glass	2.44–2.48	4800–4900/NA	85–90
GFRP, S-glass	2.54–2.60	3400–3500/NA	65–75
CFRP	1.75–1.95	2500–6000/NA	200–800
Acrylic	0.7–1.25 (1.16)	19.3–85.0 (64.3)/25.0–85.0 (60.2)	0.950–3.79 (2.69)
Polycarbonate	0.95–1.54 (1.2)	46.1–124 (64.6)/37.0–191 (64.3)	1.80–7.58 (2.37)
Unreinforced polyoxymethylene	1.14–2.23 (1.42)	5.00–115 (55.6)/22.0–120 (26.8)	0.586–12.1 (2.73)
Acrylonitrile–butadiene–styrene	0.35–3.5 (1.06)	24.1–73.1 (38)/20.0–73.1 (43.3)	0.778–6.10 (2.3)
Polyvinyl chloride	1.4	4.00–59.0/17.0–52.0	0.00159–3.24
Ceramic (96% alumina)	3.7–3.97	2070–2620/260–300	393
Metal matrix composite, Al/SiC	2.78–3.01	230–317	125–270

corrosion resistance and ease of machining and fabrication with relatively low cost. Additionally, POM has high stiffness, low friction, and excellent dimensional stability. PC and acrylic have high-impact strength. They are lightweight and flexible. Even though glass is brittle and, hence, subject to damage from impact, glass spheres are also appropriate for pressure vessels because of the immense strength-to-weight ratio, corrosion resistance, nonmagnetic and electrically non-conductive characteristics, and low cost [25.9]. Some properties are summarized in Table 25.1.

The metal corrosion in seawater is the gradual deterioration of a material based on the electrochemical reaction. There are galvanic corrosion and electrolytic corrosion which are known for fundamentally the same process and known for accelerating rates of the metal corrosion in underwater robot [25.3]. To protect against electrolytic corrosion, insulators, such as resin or rubber are attached to metal contact surfaces [25.6]. However, surface treatment is an effective way to avoid any direct contact of seawater. Anodizing is a surface conversion process that changes the exterior physical properties of a metal to form a hard coating on the surface as results of a controlled electrochemical process. One thing we should remember is that anodizing works well only when the entire surface remains intact. In other words, a small chip in the surface can become the point of accelerated corrosion if there is contact with a less active material [25.10]. A topcoat will provide additional protection against corrosion. Sacrificial anodes, made of highly active metal like zinc and magnesium, are alternative for corrosion protection. As sacrificial anodes corrode and deteriorate, they must be periodically inspected and replaced if needed.

When designing an underwater robot, it is recommended to have small positive buoyancy, except the reserve buoyancy for payload. It will help an underwater robot returning to the surface in the case of any electronics and power failure. The amount of positive buoyancy would depend on the size of robots, typically from a few hundred grams to several kilograms. There are several factors for consideration in choosing buoyancy materials, such as low density, high strength, nontoxic harmless, and weather resistance. The most important factors are low water absorption and low compressibility, which are all dependent on the target operating depth [25.4]. For an underwater robot, expandable polystyrene, polyisocyanurate foam, and syntactic foam are the most common buoyancy materials. The expandable polystyrene (EPS) is a super light and cheap material. However, it is only used for very shallow water because it is compressed by water pressure. Polyisocyanurate foams are generally low-density, insulation-grade foams, which have excellent insulating value and good compressive-strength properties. Since it is usually made in large blocks via a continuous extrusion process, these blocks are reasonably inexpensive and effective for shallow water [25.4]. The syntactic foam consists of glass microballoons and epoxy resin. The amount of trapped air within the resin structure will determine the density as well as the durability of the foam at deeper depths. It is also noted here that ballasting is a procedure of adding, removing, or relocating weights or floatation on an underwater robot to correct its buoyancy, pitch, and roll. There are two types of ballast systems: fixed (static) ballast and variable (active) ballast. In a fixed ballast system, an underwater robot is preset to the desired ballast and operates without any dynamic change of the ballast system. Fixed payload is

usually in the form of several lead blocks, which can be exchanged for equipment without adjusting the robots

buoyancy. Variable ballast is not common in most ROVs but the hybrid ROV, *Nereus*, has one [25.8].

25.3 Power Systems

Underwater robots obtain power from any of three categories: on-board power, surface power by a tether, and the combination of the two. For an onboard power system, we can think of many types of power sources, such as primary/secondary batteries, internal/external combustion engines, and fuel cells. For surface powered underwater robots, the mother ship has to deliver power to the robot by a tether. Surface powered underwater robots have advantages of high power capacity and almost unlimited power but also entail additional cost for a winch, a drum, a TMS, and a mother ship. This section reviews typical power sources including batteries, fuel cells, and surface power systems.

25.3.1 On-Board Power Sources

The on-board power source of an underwater robot is an air-independent power (AIP) system, and the most common AIP system is batteries. Performance specifications of untethered vehicles like AUVs, such as working range, service time, and payloads are limited by the battery capacity.

Battery technology has improved over the last decade. One would like to have better battery sources in terms of high energy density, high charge and discharge rates, desirable current characteristics, wide operating/storage temperature range, reliability, long lifecycle, low cost for purchasing and maintenance, and, most importantly, safety against fire and explosion. We should also consider details on safety such as nongassing, spill-proof electrolyte, status monitoring as well as special requirements depending on the shape and volume of an AUV and particular working environment conditions such as depth, under sea ice near the North Pole [25.6, 11, 13].

Primary batteries usually have better endurance than secondary batteries. The lithium primary battery has a very high energy density but its operating cost is more expensive. The alkaline battery can be considered the most common primary battery as it is relatively cheap, but it has safety issues because it outgases hydrogen and it is sensitive to temperature [25.7].

There are a number of different kinds of secondary batteries including lead-acid, silver zinc, nickel-cadmium, nickel-metal hydride, lithium-ion, lithium-polymer batteries. Lead-acid batteries are the oldest type of battery having a low energy density. How-

ever, because of its relatively large power rate and low cost, they are the popular choice for many applications. Nickel-cadmium (Ni-Cd) batteries were widely used in commercial products because of their robust characteristics but had problems with the toxicity of the heavy metal cadmium. Nickel metal hydride batteries have been improved to eliminate drawbacks of Ni-Cd and replaced Ni-Cd in the market. During the last couple of decades, the silver-zinc battery was the most used power source in professional AUVs because of its better performance compared to that of old type secondary batteries such as lead-acid and Ni-Cd, even though it is very expensive. Today, lithium-ion and lithium-polymer batteries are popular in our daily life. We can find them in many IT devices. Li-ion batteries using lithium ions as an electrolyte have the advantages of higher energy density, longer cycle life, relatively low self-discharge, low maintenance, and light weight. However, the drawbacks include protection circuits and aging effects. In contrast, lithium-polymer batteries use a solid polymer composite. This reduces the chance of overcharging and electrolyte leakage and is more robust against physical damage [25.12], even though they have a lower energy density and a lower life cycle compared to Li-ion batteries. Some properties are summarized in Table 25.2.

In the literature, as one of the alternatives, seawater batteries with very long endurance capabilities are considered and have been studied to improve the performance. However, due to low power capacity, its applications are limited [25.14].

A fuel cell is an electrochemical device converting the chemical energy of fuels with oxygen directly into electricity to produce electric power, heat, and water. Since there is continuously replenished fuel, a fuel cell has a much larger capacity and longer endurance than batteries at the cost of system complexity. There are various types of fuel cells. The most common types are solid oxide (SOFC), direct methanol (DMFC), proton exchange membrane (PEMFC), or polymer electrolyte (PEFC), phosphoric acid (PAFC), molten carbonate (MCFC), and alkaline (AFC), where each type operates at different temperature conditions using different materials [25.15, 16].

A closed-cycle PEFC system is known to be the most suitable for underwater and it consists of a fuel cell generator, a high pressure oxygen tank, and a metal hydride tank. Its operating temperature is around 60 °C

Table 25.2 Summary of characteristics of commonly used batteries (after [25.7, 11, 12])

Type	Advantages	Disadvantages	Energy/weight (W h/kg)	Energy/volume (W h/l)	Rating	Life cycle
Alkaline (primary)	Cheap	Leak gas at high temperature	140	–	–	–
Lithium (primary)	High energy density, expensive		375	–	–	–
Lead acid (secondary)	Low cost, long life cycle (1000)	Low energy density, leak hydrogen	20–30	60–80	–40–50	700
Silver–zinc (Ag–Zn) (secondary)	High energy density	Limited life cycle (40–100), need careful maintenance, high cost	100–120	180–200	–48–71	100
Nickel–cadmium (Ni–Cd) (secondary)	Long life cycle, flat discharge curve, good low temperature performance	Memory effects, environmentally unfriendly, exothermic charging process	40–60	50–150	–40–60	2000
Nickel–metal hydride (Ni–MH) (secondary)	High energy density, reduced memory effect	Self-discharging, limited discharge current	60–120	140–300	Ambient	1000
Lithium ion (secondary)	High-energy density, long life cycle, no memory effect	Aging effect	100–265	250–730	–20–45	400–1200
Lithium polymer (secondary)	Flexible form factor, light weight, Improved safety	Lower energy density compared to Li-ion	130–200	170–300	Ambient	300–3000

and its reactive product is only pure water. Urashima, the first prototype of a fuel cell-driven underwater vehicle developed by JAMSTEC, Japan, uses a solid polymer electrolyte fuel cell (PEFC) which allows 60 h endurance and 300 km cruising with max. 4 kW power, and they achieved 60 h of nonstop electric power generation and finished a sea trial [25.17]. In 2007, JAMSTEC started the research to develop a fuel cell for the second generation long-range cruising AUV (LCAUV) to cruise over 3000 km with over 600 h of continuous running [25.12].

The energy density of a fuel cell generator itself is high, but when we consider a whole fuel cell system including subsystems, such as hydrogen, oxygen, and reactant water tanks, auxiliary components, and control electronics, its energy density becomes low. Downsizing of these subsystems is needed for underwater applications. So, a hybrid fuel/battery system would be an alternative to share full loads because it allows both components to be of smaller dimensions and operates with higher efficiency using direct hydrogen and pure oxygen [25.18].

There are two types of loads: propulsion load for propulsion and hotel load for on-board computers, lights, navigation sensors, and payloads. If an AUV is operated for professional long-term missions, we need very accurate simulations for adjusting trade-offs among various constraints. Conventional lead-acid and Ni-based batteries would not be the best choice for AUVs. Instead, lithium-based batteries are the attractive solution that does not entail time-consuming estima-

tion techniques. Nonetheless, lead-acid batteries remain a practical and low-cost option for education, experimentation, and testing.

There are two options for battery installation inside an AUV. One is that they are housed in a pressure vessel, the other one is using pressure-tolerant and waterproof batteries without a pressure vessel. The latter eliminates burdens related to leakage in assembling the system, thus increases system reliability. Lithium-polymer batteries using the solid electrolyte were made without air in the packaging. Hence, they would be a candidate in designing pressure-tolerant on-board power source for AUVs [25.19].

A battery management system (BMS) is a very important subsystem for performance and safety. It monitors the internal status of voltages, current, temperatures and state of charge. Based on the above information, a BMS controls circuits for balancing and protects batteries from over-current, over/under-voltage, over/under-temperature, and any predescribed conditions. As a part of health monitoring, an on-board computer of an AUV should collect status from the BMS to reflect a power budget and health to given missions.

Just like adding volume of auxiliary systems and fuel storage units to calculate an energy density of a fuel cell, we need a measure for fair comparison of the energy density among different power sources. Since a power source is installed inside of an AUV, which should be neutrally buoyant to save the energy in operation, energy density per neutrally buoyant

Table 25.3 Summary of pros and cons of DC and AC (alternating current) (data from [25.4, 20])

Form	Pro	Con	Remarks
DC	Two conductors with less shielding in tether, low voltage drop	Current protection, difficulties in voltage step-up and down	For observation class ROV
AC	Longer transmission distances, flexibility in voltage up and down	Inductance noise, reactive losses, need subsystem for freq. converting	For deep-sea ROV

kilogram should be a reasonable unit. This means that weight and volume for buoyancy materials and pressure vessels must be added to the power source itself, and this also means that the characteristics of buoyancy materials and pressure vessels (aluminum, titanium, composite material) under considering working (or maximum) depth should be designed before or at the same time [25.21]. Between batteries and fuel cells, a semi-fuel cell can be another alternative. It is a generator, but its usability is like a battery because one reactant is stored externally and brought to the reaction cell [25.11]. Aluminum/hydrogen peroxide energy semi-fuel cells can practically generate an energy density of about 400 Wh/kg (theoretically 3418 Wh/kg) which is three times that of a lithium-ion system [25.12]. HUGIN 3000 powered by a semi-fuel cell developed by FFI (Norwegian Defense Research Establishment) [25.7] operates at 4 km down to a sea depth of 3000 m for up to 60 h. This pressure-tolerant system is very attractive in deep-water systems. But it requires trained personnel for operation and maintenance as well as special facilities and tools [25.14].

25.3.2 Surface Power Systems

In the case of ROVs, the whole power is delivered from a mother ship to the ROV through an umbilical/tether cable, offering very high power and theoretically unlimited endurance. These electrical power transmission techniques may look simple, but actually involve a highly complicated procedure for optimization. A power system determines work capability of ROV as well as operating cost, subsystem size, and safety considerations. Typically, it consists of a surface system, a tether, and a subsea system. A surface system

includes a shipboard power source (or power outlet), frequency converter, step-up transformers, and a ground fault monitoring device. A frequency converter is used only for high-frequency alternative current, but it is advantageous in handling the power of a subsea system. In a subsea system, there are step-down transformers, rectifiers, power busses, power switching devices for distribution, and a ground fault monitoring device. Also, system configuration and setup reflects the power requirement of the devices installed on a ROV including thrusters, lights, sensors and any circuits. Once again, these design parameters of a power system are not independent of each other [25.4, 20, 22, 23].

A detail configuration depends on the form of current and needed capacity. First of all, we have to make a decision on the form of current. There are three types of current for ROV systems:

1. 50/60 Hz
2. High frequency alternating current (HFAC) at 400 Hz
3. Direct current (DC).

The decision should be based on the design objectives of maximizing power transfer, efficiency and lifetime, as well as minimizing the overall system cost using steady-state analysis and transient analysis [25.20]. Table 25.3 shows pros and cons of the form of current.

Besides maximizing the power transfer to an ROV, we have to minimize the diameter of a cable, system cost, support systems on deck, and the weight of the ROV without losing a high level of electrical power quality. Therefore, most observation class ROVs use the DC power system mainly due to portability and cost, and work-class ROVs have a tendency to use a three phase AC power system.

25.4 Underwater Actuators and Sensors

It is inevitable that the overall performance of an underwater robot depends on the quality of its actuators and sensors. While one can think of different types of actuators for underwater robots, such as thrusters, water jets, and biomimetic actuators ( VIDEO 793), most underwater robots use thrusters that use propellers in-

volving hydrodynamics of water flow when generating force to move through water. It is noted that the mapping between thruster command and generated force is not linear, especially in the transient state of motion. The sensors for an underwater robot can be divided into three groups: navigation sensors, system sensors,

and mission sensors. They can also be categorized further by acoustic- or nonacoustic-based sensing. Sensing in underwater environments is very challenging, especially position sensing. There is no electromagnetic wave propagation under water except for very short ranges and, therefore, the **GPS** (global positioning system) is not available. Due to the limited performance of a single sensor, the sensor fusion approach with multiple sensors is used. For example, the inertial navigation system (**INS**) includes an **IMU** (inertial measurement unit) and a **DVL** (Doppler velocity logger) with highly complicated algorithms. The performance of optical sensing depends on the turbidity level, while acoustic sensing encounters significant challenges due to the dynamic properties and extreme nature of the ocean, such as multipath problems, variation of signal attenuation, variation of acoustic channel, nonlinear effects, and many more [25.24, 25]. This section describes underwater actuators and sensors, and their design-related issues.

25.4.1 Actuators

There are two major types of thrusters – electrical thrusters and electro-hydraulic thrusters – along with other types such as bio-inspired smart actuators and jet propulsion. The efficiency of an electro-hydraulic thruster is about 15%, while the efficiency of a fully electrical thruster is about 43% [25.13], where the definition of efficiency is the ratio of shaft mechanical power output versus electrical power input. In spite of the low energy efficiency, electro-hydraulic thrusters are preferred for large size work-class **ROVs** because of their extensive thrust and practicality in the rugged conditions of the offshore work environment. Various factors contributing to the power conversion efficiency of the hydraulic propulsion system for **ROVs** are described in [25.26].

Many small **ROVs** and **AUVs** have fully electrical thrusters because of their compact size and high efficiency. Torpedo-type **AUVs** for cruising commonly use the screw-type propellers, which generate much more power, though only in the forward direction. Small **ROVs** and **AUVs** requiring slow but fine motion typically use the propellers generating the same power in both forward/reverse directions. When two thrusters are operating on the same plane and the same direction of motion, an underwater robot must have counter-rotating thrusters to eliminate the counter torque effect of the thrusters rolling the robot opposite to the direction of propeller rotation.

There are many propeller design parameters including propeller diameter, the number of blades, blade pitch, blade thickness, hub size, rake, etc. Propeller

diameter and blade pitch are critical design parameters that impact a robot's torque and power, and are related to the size and cost of an underwater robot. Therefore, we have to find an optimum combination of propeller diameter and blade pitch, along with careful matching to a motor to have an efficient electrical propulsion system [25.27]. A typical underwater electrical thruster includes an electric motor, a motor amplifier and controller, a thruster housing typically made of aluminum or titanium, and oil-filled, drive shafts designed for watertight using magnetic coupling or dynamic seal, propellers, and ducts. The Kort nozzle has a relatively simple geometry and it performs efficiently at low speed. The Rice nozzle has a lower drag coefficient and a better geometry to promote increased thrust [25.24].

25.4.2 Nonacoustic Sensors

Various nonacoustic sensors can be considered for measuring an underwater robot's position and pose, and detecting its linear and rotational motion. Magnetic sensors are the most common to get the north direction, but are susceptible to local magnetic disturbances generated by the active elements of a robot system or any magnetized materials in the environment.

Inertial sensors are sensors based on inertia, where linear acceleration is measured by accelerometers and the rate of rotation is measured by gyroscopes without an external reference. There are several types of accelerometers, such as pendulous accelerometers, pendulous integrating gyroscope accelerometers, force rebalance accelerometers, piezoelectric accelerometers, differential capacitor accelerometers, and vibrating beam accelerometers. They have each advantages and disadvantages. Some of them can be built using either conventional mechanical type or microelectromechanical system (**MEMS**) type. **MEMS** types like capacitive-based **MEMS** accelerometers and **MEMS** vibrating beam accelerometers, show generally higher sensitivity and better resolution [25.28, 29]. A gyroscope (gyro) is used to measure angular velocity of an object. There are three main types of gyro: spinning mass, vibratory, and optical. Spinning-mass type gyros operate on the principle of conservation of angular momentum, and this mechanical type gyro shows wide performance range (0.0001 to $> 100^\circ/\text{h}$). However, it is very expensive. Vibratory (vibrating structure) type gyros use Coriolis forces that are small and of low cost because they use **MEMS** technology, but they have a limited performance range. Optical type gyros operate under the principle of the Sagnac effect, and there are two main types of optical gyros, **RLG** (ring-laser gyro) and interferometric fiber-optic gyro (**IFOG**). A **RLG** has high sensitivity

and stability, a wide range of measurement (from 0.001 to 1000°/h), excellent scale-factor stability and linearity, insensitivity to accelerations and fast turn-on (<1 s). The **RLG** technology is a mature technology, and is well established in the medium- and high-performance markets. However, **RLGs** are still complex and expensive. A fiber-optic gyro (**FOG**) can provide several important advantages of a pure solid-state device, such as reliable and low maintenance due to no moving part, no sealed cavity and no acoustic noise, and high performance. The **FOG** technologies are expected to replace many of the current **RLG**-based systems. However, one particular area where the **RLG** is expected to retain its superiority over the **FOG** is in applications requiring extremely high-scale-factor stability.

An attitude and heading reference system (**AHRS**) is a sensor providing three-dimensional (**3-D**) orientation information. Typically, it consists of (**MEMS**) gyroscopes, accelerometers, and magnetometers on all three axes, and an onboard microprocessor running a nonlinear estimation algorithm, such as an extended Kalman filter to compute the orientation. An integration drift is compensated by reference vectors, such as gravity and the earth magnetic field.

The fusion of several navigation sensors can minimize navigation errors. This sensor combination of accelerometers, gyros, navigation computer, and some electronics, called inertia navigation system (**INS**), provides estimations of velocity, position, and orientation by integrations of the linear accelerations and angular rates with an appropriate transformation between the body frame and the earth frame if given an initial position and orientation [25.12, 23]. Therefore, an **INS** is one of the most important devices for an underwater robot. Typically, the performance of an **INS** is usually rated in terms of its position error growth rate. USAF SNU84-1 categorizes **INS** units as shown in Table 25.4.

To increase the accuracy of a navigation system, an **INS** has been combined with **DVL** (Doppler velocity log). As an example, an integrated Doppler-inertial system, Marpos, calculates the relative position from a start point by dead reckoning, which shows a positioning accuracy of around 0.03% of the total distance traveled, the equivalent of 1.7 m per hour at a vehicle speed of three knots by **AUV** Maridan M600 [25.30].

Table 25.4 Performance classification of **INS** (USAF SNU84-1)

INS classification	Position error growth rate	Heading errors
Low	> 2 nm/h	> 0.2°
Medium	0.5–2 nm/h	0.05 to 0.2°
Precision	< 0.5 nm/h	< 0.05°

For the vertical motion of an underwater robot, its depth is easily measured by pressure sensors without any cumulative error. Actually, a pressure sensor measures the external pressure experienced by an underwater robot, where the two most common pressure sensor technologies are (i) strain gauges and (ii) quartz crystals. Strain gauge pressure sensors can typically attain overall accuracies of up to about 0.1% of full scale and resolutions of up to about 0.01% of full scale. Quartz crystal pressure sensors can typically attain overall accuracies of about 0.01% of full scale and overall resolution of up to about 0.0001% of full scale, that is, a resolution of one part per million [25.31]. Common units for pressure are atmosphere (atm), bar, kilopascals (kPa), pound of force per square inch (psi), Torr (= mmHg), and one atmosphere (1 atm) of pressure is 101.325 kPa and one bar (1 bar) of pressure is 100 kPa. In sea water, since pressure increases by 1 atm for every 10.0 m of depth, depth is an approximate reading of a pressure sensor multiplied by 10 m/atm. In fresh water, this simple formula underestimates the actual pressure by 2–3%, so you can get a more accurate depth by using 10.3 instead of 10 m/atm [25.3]. Measured pressure by a sensor is relative pressure. For absolute pressure, we have to add 1 atm to the sensor measurement.

Another nonacoustic sensor is an underwater computer vision system that can be considered as part of navigation sensors for underwater robots in addition to simply recording images of the underwater environment. When the underwater environment has high turbidity and insufficient and/or nonuniform light, it would not be easy to obtain enough visual information for the navigation through identifying objects, detecting obstacles, measuring distance between objects, and so on. However, when approaching its target very closely, for example, at the final stage of approaching for docking, the robot could gather useful information using a vision system.

On the other hand, underwater images are major products of underwater missions, especially for the inspection of submerged structures or observation of marine organisms, seafloor geology, etc. In this case, associating time stamp and localization data with the images increases the overall quality of the output. Because of the limited light range, it is very difficult to cover a wide area with one single shot. Thus, an image mosaicking is a popular strategy to overcome this in which several images are merged together in order to create a larger image, just as is done on Google Earth. Real-time image mosaicking is used for navigation stitches images with simple image manipulations, and high-quality image mosaicking is done by post-processing using various optimization techniques.

More recently, advanced, high-quality camera and video management systems have been developed such as HD (high definition) cameras, HD-SDI (serial digital interface) transmission through a fiber-optic cable, high-quality digital video management systems, holographic cameras, laser scanning systems, 3-D camera systems with 3-D monitors, a hybrid optical-acoustic imaging systems incorporating stereographic optical cameras, and high-resolution multibeam sonars [25.12, 32, 33]. Such developments would greatly help increasing the effectiveness of the underwater robot operation.

25.4.3 Acoustics Sensors

There are many ways to calculate the speed of an underwater robot. We can simply estimate the speed by the integral of linear acceleration from an accelerometer even though there are large accumulative errors. We can also measure the speed directly using a pitot tube velocity log, a rotor type velocity log, an electromagnetic velocity log, and an acoustic Doppler current profilers (ADCPs) [25.6], which are all water speed sensors, and are measuring speed with respect to the water, not the ground speed of a robot. ADCP provides measurements of the water’s current direction and magnitude by measuring the velocity of particles in water using principles of Doppler shift. However, Doppler velocity logs (DVLs) can be used to measure the velocity of robots moving in the water with respect to the ocean floor. Since ADCP and DVL use the same principles, typically DVL is operated in ADCP mode for a hydrographic instrument and bottom-lock mode for a navigation instrument. Since a DVL measures the Doppler shift of sonar signals reflected by the ground to obtain the velocity, there is a maximum range from seabed to the sensor, which is inversely proportional to the frequency of a signal, typically from 300 kHz to 2 MHz. Table 25.5 shows the performances of DVLs currently available in the market. Recently phased array technology in DVL has been announced and has

brought significant advantages over piston array type DVL in terms of size and weight, which have extended the areas of applications for DVLs [25.34].

There are several types of sonar systems such as single-beam directional sonar, scanning sonar, side scan sonar, multibeam sonar, interferometric sonar and synthetic aperture sonar. Single-beam sonars send a pulse of sound at a particular frequency that is reflected from the seabed, and its echo is received by a transducer. It can be implemented in the form of a single channel, for example, an altimeter measuring the distance between a robot and seabed, or multiple channels, for example, obstacle avoidance sonar measuring distances between a robot and any objects around it. A scanning sonar, that is, forward looking sonar, has a small transducer rotating on its axis and emits pulses at the particular direction, and then obtains a set of bins, where a bin represents the echo intensity returning from a specific place along the transducer axis. An image is synthesized by placing the set of bins in a Cartesian space with a set of colors assigning their intensities. On the other hand, a side scan sonar has a fixed transducer emitting fan-shaped acoustic pulses in the cross-track direction, and then the measured acoustic reflections are compiled to create an accurate image of the sea bottom. It is one of the most effective tools for quickly searching for any objects such as wreckage debris or mines on a large area of the seabed. However, it does not provide reliable information on their position [25.35].

An imaging sonar uses a fan beam typically with a 30° 3 dB beam width while retaining about 1.7° angular resolution, whereas a profiling sonar emits a spot or pencil beam with about a 1.7° 3 dB beam width from both horizontal and angular rotation, which means that it provides higher resolution measurements. A multibeam sonar has an array of transducer emitting acoustic pulses simultaneously to cover a large area. This beam pattern is wide in the across-track field and narrow in the along-track field, which is appropriate for collecting highly accurate seafloor information at the cost of the high purchasing expense and high power consumption. An interferometric sonar is one possible tool providing wide-swath coverage and high-resolution bathymetry in shallow water using the technique of superimposing two (or more) waves, which significantly improves the efficiency and safety of hydrographic survey operations. A synthetic aperture sonar (SAS) is a high-resolution acoustic imaging technique that sums multiple returns from multiple pings to produce output imagery with constant along track resolution which is independent of both range and frequency. This is a kind of artificial enlargement of a sonar array by accurate navigation data. Dual frequency technology has been announced for an imaging sonar and side scan

Table 25.5 Summary of DVL specifications available in market

Specification	Model A	Model B	Model C
Frequency	300 kHz	600 kHz	1200 kHz
Max. range	200–300 m	90–110 m	20–30 m
Velocity range	±10 m/s		
Velocity resolution	0.1 cm/s		
Accuracy	0.4% ± 2 mm/s	0.2% ± 1 mm/s	0.2% ± 1 mm/s
Average power	3–10 W	2–6 W	2–3 W

sonar, which offers more flexibility. A typical dual frequency imaging sonar uses frequency between 0.9 and 2.5 MHz to obtain medium and ultra-high-quality resolution from mid- to close-range. A side scan sonar's typical range is from 100 to 500 kHz. Based on a high-quality imaging sonar, researchers have been trying to identify underwater objects. Figure 25.2 shows a result of real-time tracking for artificial landmarks using DIDSON [25.36] (VIDEO 794), where the multiple landmarks are being tracked after being detected and recognized by a probabilistic based algorithm developed by the Korea Research Institute of Ships and Ocean Engineering (KRISO) [25.37].

Acoustic positioning systems are the popular approach to locate the underwater robot by solving a triangulation problem based on distances between an underwater robot and the preinstalled transponders. The distances are calculated by the time of flight of the acoustic signal between them, that is, half the round-trip time multiplied by the speed of sound in water. It is theoretically simple with no cumulative error. However, to obtain accurate position information, we have to have an exact understanding of the system, consideration of the inherent physical error sources, and lots of practical experience. The accuracy inherently depends on the configuration of the baseline, and the speed of sound underwater is affected by water temperature, pressure, and salinity. Additionally, in shallow water or in the highly reverberant underwater environment, multiple reflected copies of any transmitted signal reach the receiver at delayed intervals. It is known as the multipath problem. Therefore, we have to know the characteristics of the underwater acoustic environment at the work site. Before explaining the configuration of types of acoustic

positioning system, we need to review functions of its basic component. When an interrogator sends a signal, a transponder installed on the seabed or an underwater robot receives the interrogation signal, and then sends a reply signal to the interrogator. A responder is a transmitter installed on the seabed or an underwater robot just like a transponder, but it can be triggered by a hard-wired external control signal to transmit a signal. If a transmitter sends out a pulse on a particular frequency, it is called a beacon or pinger [25.4].

There are three main types of acoustic positioning systems: long baseline (LBL), short baseline (SBL), and ultrashort baseline (USBL). An LBL system determines the position by measuring the slant ranges from three or more transponders mounted widely spaced on the seabed and typically at the corners of the operations site. This results in very high positioning accuracy and robustness regardless of water depth over wide operating area. However, this system requires multiple transponders which inevitably need a long deployment/recovery time and a calibration time required at each location. An update rate is relatively long because of two-way ranging. In an SBL system, there are three or more transducers connected by wires to a central control unit; these transducers construct a baseline installed on from a large barge to a small boat. It is just like an upside down version of an LBL system without requiring any seafloor premounted transponders. However, accuracy depends on the transducer spacing and mounting method. When a wider spacing is available, the performance can be similar to LBL systems. Otherwise, the accuracy goes down. A USBL system consists of a small integrated transducer array and a transponder/responder installed on what we want to trace, where the position of the transponder/responder is calculated by the combination of a target distance by the time of flight of a received signal and a target direction by the phase shift of the received signal on each of the acoustic elements in the transceiver array, called phase-differencing. Since a small error of the target direction calculated by a USBL will become a larger position error over a great distance, it should be mounted on the bottom end of a strong and rigid transducer pole, which is installed either on the side or in some cases on the bottom of a surface vessel. Additional sensors, including high-quality IMU and GPS, have to compensate for errors due to the any changing position and orientation of the integrated transducer array.

USBL systems offer many advantages, such as low complexity, ease of use and not requiring sea floor transponders. But they have also some disadvantages. An installation of a rigid pole for mounting of a transducer array is needed and a calibration process is required to determine offsets for the precise alignment

Fig. 25.2 Result of real-time tracking for artificial landmarks using DIDSON

of a **USBL** system. Most importantly, their positioning accuracy and robustness are not as good as the **LBL** systems. In the case of range, all types are quite accurate assuming that the line of sight is maintained. However, the bearing accuracy of **LBL** systems is less than 1° , whereas **SBL** and **USBL** systems typically have $1\text{--}3^\circ$ bearing accuracy [25.4].

The **GPS** intelligent buoys (**GIB**) system is available as a promising acoustic positioning system [25.38]. The configuration of **GIB** is an inverted **LBL**, where several floating buoys equipped with submerged hydrophones and **GPS** receivers measure the time of arrivals (**TOAs**) of the acoustic signals sent by the emitter of an underwater target and from the time measurements tracked position is calculated in real time. This system allows fast and easy installation without a calibration process and a dedicated mother ship and provides real-time multiobjects tracking with a fast update rate because of one-way acoustic signals from the emitter of an underwater target to the floating buoys. The number of floating buoys is determined by the size of the area and the accuracy requirement of given operations.

25.4.4 Other Sensor Issues

Many sensors and communication devices of an underwater robot, such as altimeter, **DVL**, imaging sonar, ranging sonar, acoustic modem, and acoustic positioning system are sonar-based devices. The integration and

concurrent operation of multiple sonar sensors could cause cross-sensor acoustic interference problems. The contamination caused by such sensor crosstalk severely degrades the performance and sometimes, more seriously, mangles the whole sensor system. Basically, we have to mediate a sensor configuration including working frequencies of all sensors and their mounting positions to avoid sensor crosstalk. For mission sensors, we can selectively turn on the sensors as needed, considering other sensors installed on the mother ship. Additionally, potential problems of bio fouling and corrosion of underwater sensors should be taken into consideration and the quality of measurements should be regularly maintained.

Health-monitoring sensors are also very important. Even though they are small and relatively cheap compared to navigation sensors, it could save a robot. Health-monitoring sensors cover multipoint temperature and humidity values inside pressure vessels, status of the power system, for example, status of a battery using a battery management system (**BMS**) or status of tether cable using a ground fault-monitoring system, and status of the control system. At the same time, an emergency plan should be prepared for cases in which the system is headed toward complete failure. Examples include a situational warning for high temperature or clear thruster commands when communication is lost. An emergency beacon and a flash have to be operated independently from any system of the robot.

25.5 Computers, Communications, and Architecture

Design of computer systems, software architecture, and communication systems is a major task in designing an underwater robot. Designing the overall hardware and software structures and selecting appropriate components are very challenging and crucial. Nowadays, tethered robots or **ROVs** use a fiber-optic cable for real-time data transfer between a simple on-board computer system and a high-performance computing system on a mother ship. Untethered robots or **AUVs** require high computing power resources on-board with an underwater wireless communication system such as an acoustic modem.

It is worthwhile to note the Woods Hole Oceanographic Institute (**WHOI**)'s hybrid **ROV**, also known as *Nereus* [25.8]. It operates in two different modes. For broad area survey, the vehicle can operate untethered as an **AUV** capable of exploring and mapping the sea floor with sonars and cameras. For close-up imaging and sampling, *Nereus* can be converted at sea to operate as an **ROV**, using a lightweight, microthin, fiber-optic tether. *Nereus* uses its manipulator by tele-

operation via the fiber-optic tether while the vehicle can be considered an **AUV**. In May 2009, *Nereus* explored the Mariana Trench, being the first vehicle to explore the Mariana Trench since 1998.

25.5.1 On-Board Computers

ROVs rely on computing systems on a mother ship and typical candidates are industrial **PCs** installed on a rack or on a shelf inside a control van as a surface control system. The overall system consisting of several **PCs** with a high-speed network handles data from the **ROV** and commands from its operator in order to control the **ROV**. Each computer is designated for a certain mission such as control, navigation, etc. However, the recent trend is to simplify the interface by an integration of multiple **PCs** and by specific software with expectation of cost saving benefits [25.39].

Unlike **ROVs**, **AUVs** must have compact, robust, reliable, and high-performance on-board computer sys-

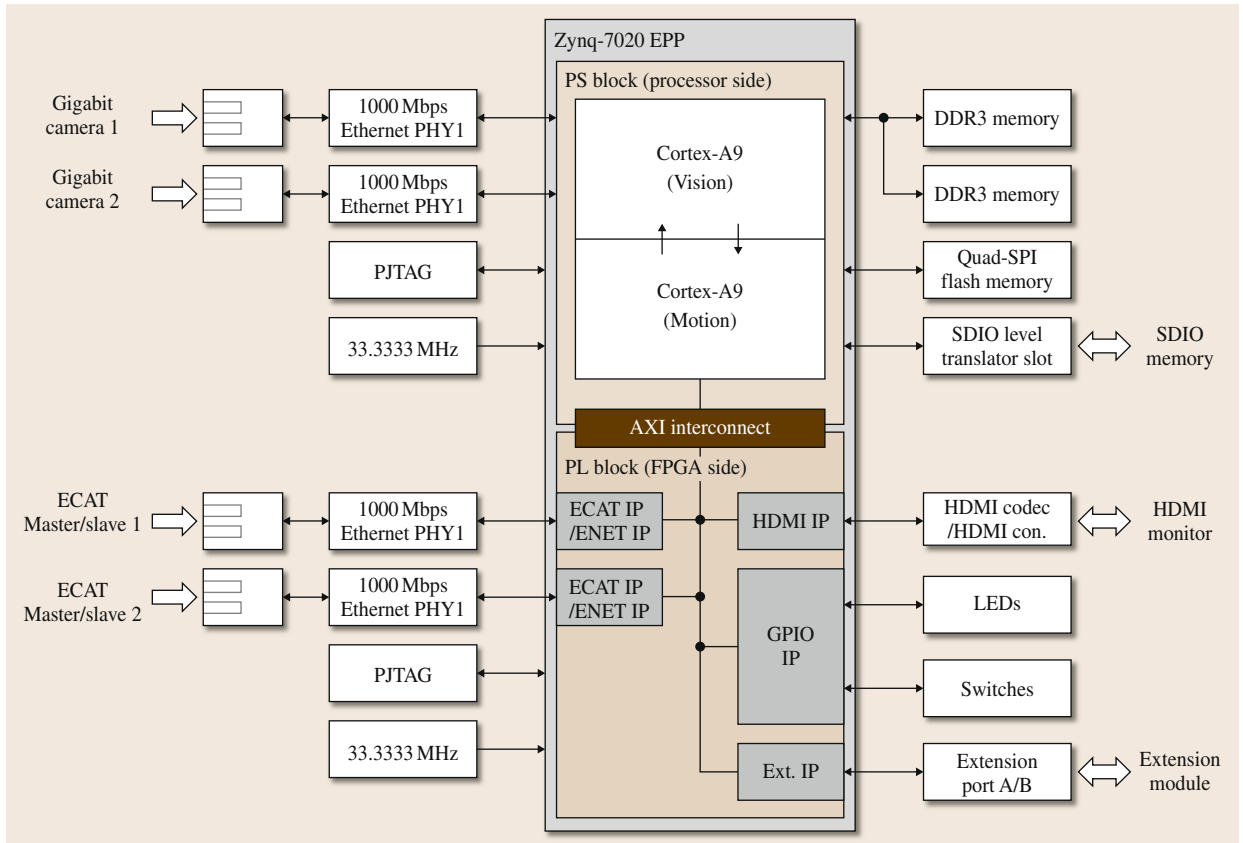

Fig. 25.3 Hardware configuration of Zynq-7020-based system, mController

tems. One popular choice is a **VMEbus** (Versa Module Europa) system [25.40]. Many **AUVs** before the year 2000 such as ODIN, Oceans Voyager II, and Aqua Explorer 1000 used a **VME** system based on Motorola **CPU** with a real-time operating system, such as VxWorks and OS9 [25.2]. Some **AUVs** like Kambara and Oberon use Compact peripheral component interconnect (**PCI**) systems [25.32, 41]. The controller area network (**CAN**) bus was originally designed as a vehicle bus standard to allow many subsystems such as actuators and sensors to communicate with each other using only two wires by a maximum 1 MHz data transmission rate [25.12]. The **CAN** bus could bring great advantages in designing the layout of wire harnesses for internal sensors of an **AUV**, but unfortunately, it has not been popular because there are few internal sensors that support it.

PC-104+ is an embedded computer standard which has no backplane but the boards are stacked on top of each other via stackable **ISA**, **PCI**, and **PCIe** bus connectors [25.33]. **PC-104+** based systems are widely used in various types of embedded applications because of their advantages such as small size, stackable, rugged, compact, interoperable, **PC** compatible high-

quality, low cost, and low power consumption [25.33, 40]. Basically, it consists of a **CPU** board with an optional power supply module. Other required functions can be added by stacking multiple peripheral modules such as frame-grabber, analog digital converter/digital analog converter (**ADC/DAC**) converter, digital **IO**, relay, serial communication, **CAN** network, and **GPS** receiver from different manufacturers. Each module offers high-performance specifications and environmental specifications, such as extended operating temperature from -40 to $+85^{\circ}\text{C}$. As an example, a decade ago, ODIN, originally developed with a **VME**-based on-board computer system, was refurbished to a **PC-104+** based **AUV**, ODIN III [25.42]. Today, many recently developed **AUVs** employ **PC-104+** based systems. It is also noted that as a possibility of a heterogeneous bus system, there is a **PC-104+** bus-based system (**CPU** module) along with standard **VME**-based I/O modules using a protocol interface card [25.40].

PC-104+ is a good choice for a single **CPU** system. However, when we need more computing power for implementing complicated algorithms, additional **PC-104s** must be installed because multiple **CPU**s

Fig. 25.4 Typical diagram of fiber-optic communication system for ROV

are not supported in a PC-104+ stack. For example, yShark [25.43] has three PC104+s with a high-speed local area network (LAN) for robot control, image processing, and acoustic signal processing. This causes many difficulties, such as a complicated system structure, wiring, space, and cooling in a pressure vessel. Alternative design of a distributed on-board system for an AUV is a combination of a PC-104+ system and an ARM-based system. Besides consumer mobile devices, many mobile robots have used ARM processors 32-bit RISC (reduced instruction set computer) microprocessors because of its high-performance, low power consumption, and low cost. As an example, Fig. 25.3 shows a hardware configuration of mController (announced by Redone technology, Korea) which is based on the Xilinx Zynq-7020 platform [25.44]. Its size is only 125 mm × 125 mm, and it consists of Dual core Cortex-A9 for typical motion control and vision processing, and an FPGA part for data parsing of various sensors. In this hardware hierarchy, PC-104 could be designated to operate high-level tasks.

An on-board-independent microcomputer-based emergency response system is very important to carry out critical functions, such as power disconnection of thrusters and weight drop when the on-board main system is dead. The emergency response system consists of a microprocessor that monitors the status of the on-board main system, an actuator, and a backup battery. Under normal conditions, the on-board main system would regularly check the status of the emergency response system.

25.5.2 Communications

For ROVs, an umbilical cable is used for communication between an ROV and its mother ship. An umbilical cable commonly has a coaxial core or a fiber-optic core. A fiber-optic cable is much better than a coaxial cable in terms of performance and physical dimensions. Light and thin fiber-optic cables offer high-speed, secured, long-distance data transmission without electromagnetic interference, and less drag force on an ROV, even though it is an expensive solution mainly because of op-

tic fiber distribution devices, fiber-optic tools, and the special knowledge required for a handling fiber core. An umbilical cable of a typical ROV has been designed to have 2–3 fiber-optic cores including a spare core. A fiber-optic modem connected to each end of a fiber-optic cable sends and receives data at the same time, working together with several sub-boards that convert data in various formats, for examples, NTSC Video, RS232, and LAN as shown in Fig. 25.4.

Since the demand of high-quality video, such as multiple HD video, 3-D HD video, and UHD (ultrahigh definition) video is rapidly increasing, 100 Gbps optical communication systems are released to handle mass data using a technology known as dense wave division multiplex (DWDM) [25.12]. Cable designers are also making an effort in developing new techniques to add more fiber-optic cores inside an umbilical cable, where each core could be designated to high-quality video devices. The Nereus team used a light fiber tether system to send a lightweight battery-powered vehicle to the full depth of the ocean of about 11 km in the ROV mode. The selected Sanmina/SCI buffered fiber is 0.25 mm in diameter, weighs only 0.173 kg for 11 km cable in water, has a working strength of 8 N, and a breaking strength of 108 N [25.5].

For untethered vehicles like AUVs, wireless communication is considered. Typical radio communication would be fine when an AUV is on the surface. In an underwater environment, acoustic communication is the practical solution at the moment even though a commercial acoustic modem has a limited range and a very limited data rate. Table 25.6 shows the specifications of commercial acoustic modems. Acoustic communication is relatively slow compared to radio communication, and it is fundamentally limited by the speed of sound in water, roughly 1500 m/s. Because acoustic attenuation increases with sound frequency, lower frequencies are desirable for long-range communications. But, to generate signals at very low frequencies, larger size transducers are needed. This results in lower data rates that are undesirable [25.2, 13]. The speed and direction of sound propagation vary depending on various factors such as surface waves, currents, sea state, tides,

Table 25.6 Specifications of commercial acoustic modems

Specification	A modem	B modem	C modem	D modem
Size (length × dia)	585 × 183	200 × 165	235 × 126(87)	580 × 150
Material	Aluminum	Aluminum		
Weight (air/water)	11/6	5/1.5	4.2/2.3	21/(n/a)
Voltage	18–50 V _{DC}	10–20 V _{DC}	12–24 V _{DC}	18–28V _{DC}
Power (transmit/receive/sleep)	< 50 W/1/0.03	20/0.6/0.005	2/0.75/0.008	40/0.9/0.009
Working depth	3000	1000	200	7000
Working temperature (°C)	–5–40	–5–40	–5–45	–5–45
Beam width	±25	Hemispherical	210 (Omni)/120 (wide)/70 (narrow)	210 (Omni)/70 (Directional)
Working range	7000 m	Up to 20 km	350 mm	7000 m (Omni)/10 000 m(D)
Frequency	14–22 kHz	7.5–12 kHz	26.77–44.62 kHz	7.5–12.5 kHz

Environment			Near vertical, horizontal	Near vertical, horizontal

DPSK: differential phase shift keying

temperature, conductivity, depth, and sea-bottom type. Hence, acoustic communication is inherently delayed, due to propagation delay. Several techniques in signal processing, data packaging, and coding schemes have been developed to overcome these difficulties due to signal absorption, geometric spreading losses, boundary effects, and multipath through.

Acoustic modems consist of three main parts: an underwater transducer, an analog transceiver including a matching preamp and an amplifier, and a hardware platform for control and signal processing, such as microprocessor, digital signal processor (**DSP**), or field programmable gate array (**FPGA**) [25.45]. When acoustic communication technology was in its infancy, an analog-based hardware platform was developed. Then digital techniques brought important improvements for increasing the reliability of transmissions using explicit error-correction techniques and increasing some level of compensation for the channel reverberation both in time (multipath) and frequency (Doppler spreading) [25.46]. There are several methods in digital modulation, where the most fundamental techniques are **PSK** (phase shift keying), **FSK** (frequency shift keying), **ASK** (amplitude shift keying), and quadrature amplitude modulation (**QAM**), and their improved versions are **MFSK** (multiple **FSK**), **QPSK** (quadrature phase shift keying), **MPSK** (M-ary phase shift keying), **MSK** (minimum shift keying), **GMSK** (Gaussian minimum shift keying), **MQAM** (M-ary quadrature amplitude modulation), and so on.

Just like a typical network, a data packet is packed with a header and a tail for addressing, error detection and correction not to be corrupted by transmis-

sion errors. In particular, the data link layer protocol implemented in some modems detects errors in a received packet and then requests retransmissions, which degrades the effective transfer rate. To reduce the retransmission rate, some modems have a function to adjust the speed of transmission depending on the channel condition. Another important technique is about minimizing the effects of multipath, which is most prominent over long ranges and shallow water because the original signal can be bounced between the surface and bottom before arriving at the receiver. There are a few algorithms for robust data transmission in multipath environments, such as convolutional coding, multipath guard period, and data redundancy. Also, a time-reversal technique is an alternative to reducing the effects of multipath [25.12]. From a practical point of view, acoustic communication has some other limitations, such as horizontal communication in shallow water, the loss of line of sight between the modems, the in-band noise (typically caused by another sonar system), echo sounder from ships, a shallow zone, and clouds of air bubbles near a receiver. These limitations might degrade its performance or make it unreliable.

Electromagnetic waves are strongly absorbed by sea water, but, for close-range communication, electromagnetic communication would be useful because it would be less affected by multipass interferences. **JAM-STEAC** (Japan Agency for Marine-Earth Science and Technology) has developed a new communication using electromagnetic waves. This was experimentally evaluated up to 50 m distance [25.12].

Another approach is an optical underwater communication that achieves much higher data transfer rates

than an acoustic communication system at significantly lower power consumption and smaller packaging. However, the operation requires a point-to-point communication setting, requiring the alignment of the receiver and the transmitter for the communication to work effectively. Their range and scope are also affected by the water clarity, water light absorption, and power loss due to propagation spherical spreading [25.47]. Recently, the Massachusetts Institute of Technology (MIT) proposed a real-time video delivery solution based on underwater optical communication, AquaOptical II that consists of a high-bandwidth wireless optical communication device and a two-layer digital encoding scheme designed for error-resistant communication of high-resolution images. Its maximum transmission bandwidth of 4 Mbps and various video streaming tests showed similar performances at close ranges of up to 25 m in a pool trial [25.48], and up to 3–4 m on the Charles River near Boston. It requires accurate motion stabilization because of the narrow beams involved [25.49].

When an AUV is on the surface or an AUV exposes an antenna above the surface, radio communication is the best option. For a short range in which an AUV is operating near shore or its support craft, 900 MHz wireless modems or 2.4 GHz 802.11 wireless networks are common considering antenna sizes [25.49]. For longer ranges, radio links make use of an earth orbiter satellite like Argos satellites and Iridium satellites. In some cases, we have to make our own pressure-tight antenna, including a motion stabilizer to track the satellite regardless of fluctuation of motion. A tracking system for the *Urashima* vehicle was developed using data on network design and the oscillating characteristics of the vehicle [25.12]. Oscillation of the vehicle was measured with the high-accuracy inertial navigation system installed in *Urashima* in a sea trial. An oscillation angle of 7° and period of 0.15 Hz were estimated.

25.5.3 Software Architecture

includes various software components as shown in Fig. 25.5. The lower part of the software architecture is middleware as a class of software technologies designed to help managing the complexity and heterogeneity inherent in distributed systems [25.50]. It is defined as a layer of software above an operating system but below application programs that provide a common programming abstraction across a distributed system.

In the literature, AUV architectures were classified into four categories – the hierarchical architecture, the hierarchical architecture, the subsumption architecture, and the hybrid architecture [25.51] or into three categories – the deliberative architecture, the reactive

architecture, and the hybrid architecture [25.52]. Since most of the recently developed architectures are hybrid, instead of describing each architecture, key features of recently proposed software architectures for AUVs are described below.

Teleo-Reactive EXecutive (T-REX) was developed for a specific underwater robot by the Monterey Bay Aquarium Research Institute [25.53–55]. It is a goal-oriented hybrid executive with an embedded automated planning adaptive execution using agents. In order to make the embedded automated planning scalable, the T-REX enables the scope of deliberation to be partitioned functionally and temporally inside units called Teleo-reactors. A Teleo-reactor agent is considered the coordinator of a set of concurrent control loops, which is characterized by functional scope, temporal scope, and timing requirements.

Huxley was developed by Bluefin Robotics originally for its fleet of AUVs. Since it is for their wide range of commercial products, the most fundamental requirement was the flexibility in terms of robustness and reliability, extensibility for new hardware, maintainability, and testability [25.56]. It consists of two layers – a reactive layer and an executive layer – and it allows expanding these core layers through a standard interface. Another key element is the Huxley messaging protocol, called the stream-oriented messaging architecture (SOMA), where SOMA is a publish-subscribe messaging protocol. Huxley's layered architecture with SOMA and SOMA interfaces can be extended along with new functionalities and/or modified configurations of future AUVs while localizing changes and increasing the reusability of components.

The lightweight communications and marshalling (LCM) system was designed as an alternative for implementing inter-process communication (IPC) for real-time robotics in the marine environment. It was

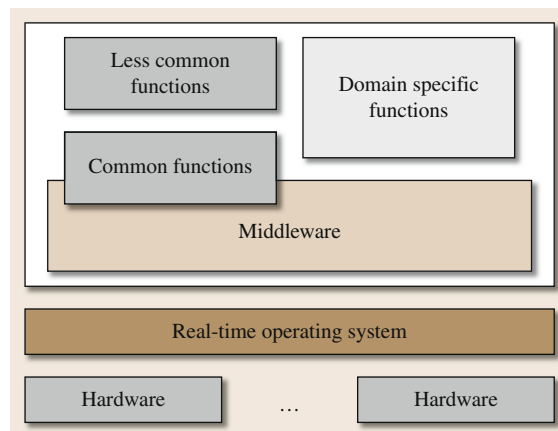

Fig. 25.5 Typical configuration of software for robot

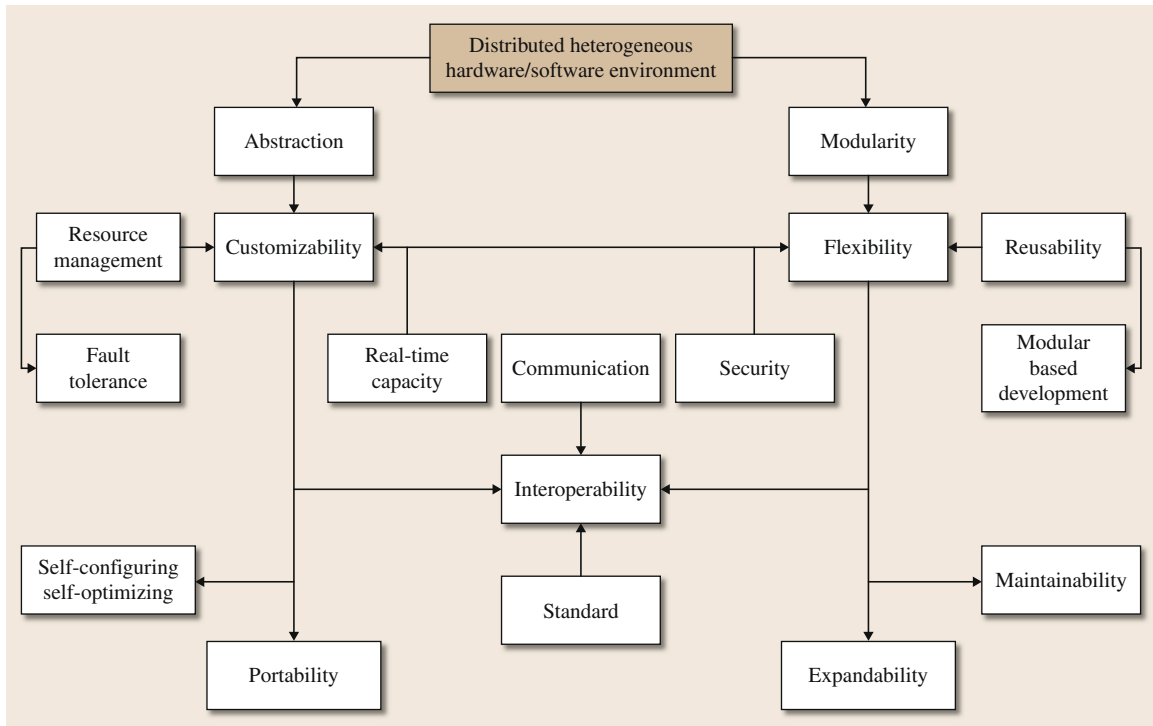

Fig. 25.6 Key characteristics of middleware

developed specifically for low-latency, high-throughput communication accomplished by a set of software tools for message passing between modules using user datagram protocol (UDP) multicast, marshalling (encoding and decoding) of LCM messages, language-independent data structures for messages of any digital data, allowing the transparent distribution of the system. This architecture was verified by two marine robotics applications [25.57].

MOOS-IvP consists of two distinct open source software projects. The Mission Oriented Operating Suite (MOOS) is, as a core middleware, a suite of libraries and executables developed by the Mobile Robotics Group at the University of Oxford. It provides inter-process communication using a publish-subscribe model, as a star topology where all messages go through a central MOOS server. IvP (interval programming) refers to a multiobjective optimization method used by the IvP helm for arbitrating between competing behaviors in its behavior-based architecture. MOOS provides modules for navigation, control and data logging, tools for mission replay from log files and communication debugging, and also provides driver modules for some sensors widely used with AUVs [25.57–59]. MOOS-IvP has been used for several AUVs including the Bluefin 21 in. UUV, the Hydroid REMUS-100 and REMUS-600 UUVs, the Ocean Server Iver2 UUV, the

Ocean Explorer 21 in. UUV, autonomous kayaks from Robotic Marine Systems and SARA Inc., and two larger USVs from the NATO Underwater Research Center in La Spezia Italy [25.54, 58].

Let us look at middleware that should be easy to use, robust against change, reliable for any faults, easy to maintain, efficiently flexible, and supportive for heterogeneous and distributed hardware components. Well-structured proven middleware with some often-needed and value-added functions would minimize time and cost for development. In the literature [25.50–53, 56–58, 60–64], there are many demanded characteristics to realize above expectations, as shown in Fig. 25.6. Fundamental characteristics of middleware are abstraction and modularity. Abstraction is expected to simplify and to lessen burdens of application development process, and modularity is a necessary condition of flexibility and customizability. Abstraction allows developers to concentrate on building advanced algorithms themselves by hiding details of low-level hardware resources of heterogeneous and distributed hardware environments [25.51, 62]. This concept includes more specified subissues: interoperability by using simplified interfaces with communication and standard; customizability with real-time capacity; and flexibility and resource management. Additionally, resource management handles faults in hardware. From these characteristics,

a middleware is free from the specific hardware environments, and could obtain portability, self-configuring and self-optimizing. To achieve flexibility, we have to follow a modular-based development for increasing reusability of existing components based on modularity and interoperability. This development approach allows us to focus on building modules without considering specific relationships between existing modules. Based on this, expandability and maintainability can be realized, where expandability is the ability to incorporate new resources, for example, newly developed sensors without interfering with the existing parts, and maintainability is about how easy to embrace modification of components without affecting the rest. To implement a middleware, standards such as the common object request broker architecture (CORBA), the Internet communications engine (ICE), and the open dynamics engine (ODE) are applied [25.64], which bring many advantages. Basically, it requires less effort in implementing and evaluating a core engine from scratch, and some of these have additional functionalities such as standardized interface and security. Security aspects such as authentication, authorization, and secure communication become essential for collaborations of multiple robots or classified applications [25.64]. So far, many research groups have proposed their own middleware for their robots, such as MIRO (middleware for robot), ORCA (open robot control architecture), UPnP (universal plug and play), RT (robot-technology), the player and stage, OPRoS (the open platform for robotic services), ROS (robot operating system), ORO-COS (open robot control software), ERSF, MRDS (Microsoft robotics developers studio), MOOS (the mission oriented operating suite), and Webots [25.50].

A development of middleware itself is not a trivial work. Understanding concepts is one thing and implementing them is another. The reasons for possible errors are mainly:

1. Many inherently distributed and heterogeneous components which will vary to improve performance.
2. The limited and restricted resources available on a robot platform.
3. The high rate of system failures from incorporating complicated algorithms and interacting with the environment, causing exceptional situations [25.50, 62].

Basically, an underwater robot's middleware has almost the same requirements as a robot, but the weighting of requirements and the point of view of requirements are little different. For an underwater robot's middleware, the following points must be considered:

1. *Limitation of resources:* Underwater robots use a low bandwidth of an underwater communication and thus, has to manage a mission using internal computing resources.
2. *Unstable sensor information:* Underwater sensors based on sonar are not stable and accurate enough to directly use data for robot control systems. Therefore, assisting algorithms such as well-tuned filtering algorithms and sensor fusion algorithms are needed.
3. *Lack of accessibility:* Underwater robots do not allow any access of an electrical contact used for debugging because of its water-proof pressure vessel.

This is one of the most challenging aspects in building an underwater robot. Thus, for the underwater robot, middleware should provide an independent channel for a supporting a debugging process.

No middleware is perfect, but we believe that we can achieve significant improvements through trial and error coupled with extensive feedback from the community [25.50]. When you develop system software and its architecture on your own, the implementation of abstraction and modularity can be understood with the white-box framework and the black-box framework concepts. The black-box framework supports extensibility by defining interfaces for components without detail information inside the components. White-box, as a base class in a class library can be designed for expanding with subclasses, based on object-oriented language features [25.63]. In the early stage of development, software architecture is mainly conceived as a white box framework. Hence, information inside the boxes, that is, classes, should be understood. As the architecture becomes more advanced and the components become more concrete, the black-box framework is the solution for most common expansions. At the moment, MOOS-IvP would be the best choice to start developing your vehicle software because it is open source software, and there is a relative wealth of information and case examples for AUVs online.

As an alternative to formal software architectures discussed above, we propose a simple but effective solution in testing a robot as shown in Fig. 25.7. This architecture has one real-time thread with several non-real-time threads for controlling actuators and devices installed on the robot.

In the Fig. 25.7:

1. The packet conveys three types of commands from an operator – commands for teleoperation, commands for RT-thread (real-time thread) itself and

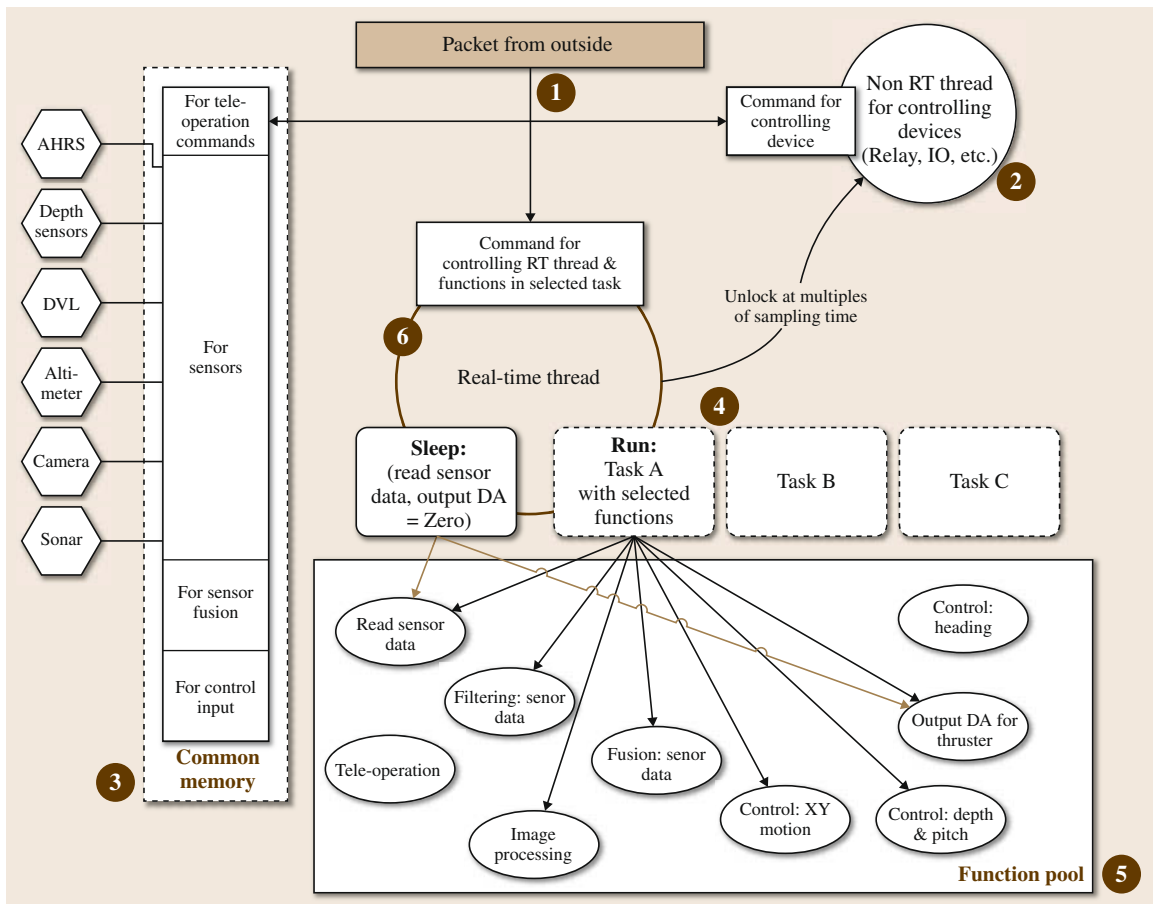

Fig. 25.7 Example diagram of simple software architecture

- functions in the selected tasks, and commands for devices of the robot.
2. Device control commands run in a non-RT thread triggered by the RT-thread, typically every 1 s.
 3. All sensor data including teleoperation commands and results of any sensor fusion algorithms are independently saved in common memory, and thruster commands, that is, control input are also saved here.
 4. This architecture has a manual task coordinator and each task can be easily synthesized using functions from a function pool.
 5. A robot is basically in one of two modes, sleep and run, where the sleep mode is doing only health-monitoring with basic sensors, the run mode runs a selected task which consists of subtasks in function pool. Tasks are designed for specific purposes, and one of them is selected by an operator before running. Of course, the default task should be the teleoperation task.
 6. The RT-thread carries three main functions: doing any critical device control commands first, DA converting for control input of previous sampling time saved in the common memory, and processing algorithms using a sensor input saved in the common memory.

Since the function of this RT-thread is based on a basic sampling time, we could easily implement any multisampling time structures for various latency times of sensors and load-distributing structures to enhance the usage of computing resources. This would be done by calling functions at multiples of the basic sampling time. This architecture has been applied to several test-bed AUVs and smart ROVs [25.42, 43, 65] (VIDEO 797, VIDEO 799).

25.6 Underwater Manipulators

Most commercial underwater robots with manipulators are ROVs. A typical work-class ROV for intervention missions has a 7 degrees-of-freedom (DOF) manipulator and a 5 DOF grabber. The manipulator is used for interactive manipulation by a human operator on the mother ship, while the grabber is used to maintain a relative position of ROV to the target object by grabbing a target structure in the presence of an underwater current or wave. This section describes underwater manipulator systems based on materials presented in [25.66]. Table 25.7 lists samples of heavy duty underwater manipulators currently available in the market. They are quite expensive but utilize proven technologies in the field. However, most commercial underwater manipulators are hydraulic-driven and developed for ROVs and they are not suitable for AUVs that have limited on-board power and whose on-board sensors could be sensitive to noise. Therefore, electric-driven manipulators would be preferred for AUVs like SAUVIM.

A typical work-class ROV for intervention missions requires two individual operators, one steering the vehicle and the other operating the manipulator. One of the main tasks of the vehicle operator is to keep the ROV as steady as possible (station-keeping) since the vehicle motion can disturb the manipulator and greatly affects the accuracy of its end-effector interacting with the environment. The accuracy of the end-effector would be greatly improved if the manipulator controller could compensate for any disturbance due to the motion of the vehicle. However, most commercial ROV systems do not use vehicle motion compensation control for the manipulator. In the past, a very few AUV systems for intervention missions have been reported and they were used as a test-bed for developing autonomous manipulation or as a working model for research.

25.6.1 Dynamics

The analysis of the dynamics of underwater vehicle manipulators is much more complex than that of regular manipulators on the factory floor. For example, it is difficult to accurately introduce the effects of the added mass and the added moment of inertia in the modeling process for multiple links of the manipulator. The frictional force and the drag force due to the velocity of the manipulator itself, waves, and currents are also complex in modeling. The modeling and control of underwater manipulators were studied by several researchers, including [25.67–78]. In this section, it is not our intention to derive details of the full dynamic equations of the underwater vehicle manipulators. Instead, we would like to point out several specific elements that

differentiate underwater vehicle manipulators from regular manipulators. The hydrodynamic forces acting on a rigid body moving in fluid can be found in [25.79, 80]. Similar to the vehicle main body, each link of the manipulator will be influenced by hydrodynamic forces including added mass, buoyancy acting at the center of buoyancy of the link, the fluid acceleration force resulting from the acceleration of the fluid itself, and the fluid drag forces exerted on the link.

As the profile drag forces are dominant for slowly moving objects, the drag force exerting on an infinitesimal element of the i -th link and the total drag force on the link can be expressed as

$$dD_{fi} = \frac{1}{2} \rho C_D b_i v_{ti} |v_{ti}| dx, \quad (25.1)$$

$$D_{fi} = \frac{1}{2} \rho \int_0^l C_D b_i v_{ti} |v_{ti}| dx, \quad (25.2)$$

where C_D is the drag coefficient, ρ is the fluid density, v_{ti} is the relative velocity of the element to the fluid flow velocity, $b_i dx$ is a projected area of the element, and l is the link length.

Considering the effects of the hydrodynamic variables above and assuming that the vehicle is stationary during the manipulation, the dynamic model of an underwater manipulator having a series of links and joints can be represented by the following equations,

$$\mathbf{M}_m(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}_m(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{D}_m(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{F}_m(\dot{\mathbf{q}}) + \mathbf{G}_m(\mathbf{q}) + \boldsymbol{\tau}_d = \boldsymbol{\tau}_m, \quad (25.3)$$

where $\mathbf{q} \in \mathbf{R}^{n \times 1}$ is a joint angle vector, $\boldsymbol{\tau}_m \in \mathbf{R}^{n \times 1}$ a joint torque vector, $\mathbf{M}_m(\mathbf{q}) \in \mathbf{R}^{n \times n}$ an inertia matrix including added mass terms, $\mathbf{C}_m(\mathbf{q}, \dot{\mathbf{q}}) \in \mathbf{R}^{n \times 1}$ a nonlinear vector arising from centrifugal and Coriolis effects including added mass terms, $\mathbf{D}_m(\mathbf{q}, \dot{\mathbf{q}}) \in \mathbf{R}^{n \times 1}$ a nonlinear vector due to hydrodynamic forces, such as drag forces, $\mathbf{F}_m(\dot{\mathbf{q}}) \in \mathbf{R}^{n \times 1}$ a nonlinear vector due to friction at the manipulator joints, $\mathbf{G}_m(\mathbf{q}) \in \mathbf{R}^{n \times 1}$ a nonlinear vector due to gravity and buoyancy forces, $\boldsymbol{\tau}_d \in \mathbf{R}^{n \times 1}$ a vector of unknown signals due to unmodeled dynamics or external disturbances such as current.

During the manipulation, the end-effector or tool of the manipulator can be in contact with the environment, and forces and moments would occur at the end-effector. In this situation, (25.3) must be modified by adding the reaction torque to the end-effector force on the right-hand side of (25.3)

$$\boldsymbol{\tau}_r = \mathbf{J}_m^T(\mathbf{q}) \mathbf{f}_e, \quad (25.4)$$

Table 25.7 Samples of commercially available underwater manipulators

Specification	Eca robotics	International submarine engineering (ISE)	Kraft telerobotics	FMC/Schilling robotics	Western space and marine
Model	Arm 7H	Magnum-7	Predator	Titan 4	The ARM
DOF	6 plus gripper	6 plus gripper	6 plus gripper	6 plus gripper	6 plus gripper

where $\mathbf{J}_m \in \mathbf{R}^{6 \times n}$ is the manipulator Jacobian matrix, and $\mathbf{f}_e \in \mathbf{R}^{6 \times 1}$ a vector of forces, and torques at the end-effector.

The dynamics of the underwater vehicle manipulator is quite complicated, highly nonlinear, and involves coupled equations with unknown parameters and disturbances as shown in (25.3). It is almost impossible to accurately model the dynamic equations and to operate the manipulator at a nominal speed using a conventional controller. However, when the manipulator moves very slowly in a friendly environment with no or minimal current or wave, the dynamics of the manipulator can be represented by the simplified linear version of (25.3) since the effect of velocity-dependent terms become negligible. In fact, during the actual operation in the field, most commercial underwater manipulators move very slowly (much less than 1 rad/s) for safety and other reasons, and they use conventional joint controllers for the master-slave teleoperation.

25.6.2 Teleoperation

A typical setup for teleoperation involves the operator sitting in the control room located on the mother ship and holding a master arm that is a miniature of the actual underwater vehicle manipulator (slave arm) at-

tached to the ROV. The operator controls the slave arm by moving the master arm and its motion is followed by the slave arm. During the operation, the operator relies on visual information of the work site in the form of a series of two-dimensional (2-D) video images that are captured by cameras on the vehicle main body and the slave arm. The images are then transmitted to the control room monitors by an underwater cable. The view of the work site is not only limited, but the visual information especially for the deep sea operation is also often delayed. If the vehicle is not holding or sitting on an underwater structure, the ROV operator must try to control the vehicle for station-keeping during the manipulation. However, even if there is no current or wave during the station-keeping, the vehicle moves like free floating within the accuracy of the vehicle position sensors in the order of a meter or so. Therefore, it is difficult to achieve the accuracy at the end-effector since underwater vehicle manipulators are attached to the vehicles that are constantly moving, unlike industrial manipulators, whose bases are fixed on the factory floor. As mentioned in [25.81], many simple tasks on the ground such as plugging become very difficult to perform by the underwater vehicle manipulator. Underwater plugging tasks, done on a trial-error basis as the required precision cannot be achieved by the ROV manipulator

system, take hours to complete. Therefore, operator fatigue often becomes a critical issue in tele-operating the underwater vehicle manipulator.

25.6.3 Autonomous Manipulation

Autonomous manipulation on a moving base, such as terrestrial mobile robots, humanoids, and underwater robotic vehicles is a very challenging task in the area of robotics in general, especially in unstructured environments, such as underwater. It is defined as the capability of a robot system that performs intervention tasks requiring physical contact with unstructured environments without continuous human supervision. Unlike industrial manipulators which have fixed bases on the floor, autonomous manipulation requires a system capable of assessing a situation, including self-calibration based on sensory information, and executing or revising a course of manipulating action without continuous human intervention. Therefore, developing a system capable of fully autonomous manipulation would be a great achievement and make a substantial impact on a variety of application areas with significant economical, societal, and scientific importance [25.82].

Let us look at one scenario of cutting an underwater cable. With given information about the cable's location and shape, the vehicle has to navigate to the location,

identify the cable, position itself, and cut the cable. It may sound like a very simple task. However, it would not be so simple if it has to be done in autonomous mode. Even in teleoperation mode, it would not be an easy task without the coordinated motion control if the vehicle is floating in water. In fact, the low bandwidth and significant time delay inherent in acoustic subsea communications represent a considerable obstacle to remotely operate a manipulation system, making it impossible for remote controllers to react to problems in a timely manner. Nevertheless, robots for autonomous underwater intervention would pave the way for a different range of new operations, such as deep-ocean and under-ice exploration, tasks in hazardous areas, tasks in natural or man-made disastrous regions, automated searches, and surveillance missions, to name a few.

In the past, many researchers have studied advanced control of AUV itself as reported in [25.83–91], but only a few AUVs with manipulators were introduced. OTTER is an AUV equipped with a single degree-of-freedom arm, which was designed to be used as a test-bed for developing autonomous technologies at

Fig. 25.8 The SAUVIM vehicle (Sand Island, Hawaii, 2008)

Fig. 25.9 Girona 500 I-AUV

the Stanford Aerospace Robotics Lab in 1996. It is a hovering-capable underwater vehicle that operates in a test tank at the Monterey Bay Aquarium Research Institute (MBARI) [25.92]. Another intervention AUV, namely ALIVE, was developed by Cybernetix in 2003. The aim of the EU-funded ALIVE project was to develop an intervention-AUV capable of docking to a subsea structure, which has not been specifically modified for AUV use. A description of the ALIVE vehicle was given in [25.93].

The key technology in underwater intervention performed with autonomous vehicles is autonomous manipulation. In the literature, no such system fully functional for autonomous manipulation was reported until recent developments with a semi-autonomous underwater vehicle for intervention missions, SAUVIM [25.94–97]. SAUVIM (Fig. 25.8) funded by the US Office of Naval Research was jointly developed by the Autonomous Systems Laboratory (ASL) of the University of Hawaii, Marine Autonomous Systems Engineering (MASE), Inc. in Hawaii, and Naval Undersea Warfare Center Division Newport (NUWC) in Rhode Island. The first fully autonomous manipulation in an un-

structured ocean environment was demonstrated with SAUVIM at Snug Harbor, Honolulu, Hawaii on January 20, 2010. Following its success, more underwater vehicles having the capability of autonomous manipulation are expected to develop in the near future. Among some exemplar, underwater intervention tasks are object recovery/rescue, and maintenance/repairing of underwater facilities. Therefore, one may consider a task like black-box recovery, grasping an object of interest and placing it at a desired location for benchmarks in future development. One recent development after SAUVIM is the TRIDENT project [25.98–101] in Europe, which developed Girona 500 I-AUV (Fig. 25.9). They performed an autonomous underwater intervention task, with a black-box recovery in Port de Sóllers harbor (Mallorca) in October 2012 [25.14].

As subsea business in oil and gas industry is about to boom in the very near future, AUVs for intervention missions will receive more attention. While autonomous underwater manipulation is still an active research topic, recent development with SAUVIM and Girona 500 I-AUV would accelerate advancement in the field.

25.7 Conclusions and Further Reading

In this chapter, we described major subsystems of underwater robots – mechanical systems, power systems, actuators, sensors, computing systems, software architecture, communications, and manipulator systems, and also discussed critical design issues from the authors' practical experiences.

There are currently more than 1000 work-class ROVs. They are used for various applications, such as scientific research, military operations, and underwater constructions. About 57% of ROVs are used for offshore oil and gas industry. Most commercial ROVs have used old but proven technologies in the past 20 years. However, the ROV operation is very expensive as it requires a mother ship and, therefore, developing advanced ROVs or smart ROVs for efficient operations in terms of operating hours and costs has received much attention. There are more than 550 AUVs in use worldwide and some of them are commercially available. While the use of AUVs is still limited, advantages of AUVs have been recognized by the recent AUV operations in the field: post-incident monitoring of BP Macondo oil leakage in 2010 and the successful recovery of black boxes of Air France flight 447 that crashed into the Atlantic Ocean in 2009. Therefore, it is expected to see more underwater robots for various applications in the future.

Some web-based resources related to the topics of this chapter include the following sites: the Remotely Operated Vehicles Committee of the Marine Technology Society (<http://www.rov.org/>), the Autonomous Undersea Vehicles Application Center (AUVAC, <http://www.auvac.org>) and the technical committee on Marine Robotics of the IEEE Society of Robotics and Automation (<http://webuser.unicas.it/MarineRoboticsTC>). A list of AUVs and developers can be found at <http://www.transitport.net/Lists/AUVs.Org.html>. AUVSI (Association for Unmanned Vehicle Systems International) and ONR (US Office of Naval Research) sponsor International Autonomous Underwater Vehicle Competition as well as Autonomous Surface Vehicle competition (<http://www.auvsifoundation.org/AUVSI/FOUNDATION/Competitions/>).

It is worthwhile to note that several important initiatives [25.1, 101] in underwater robotics in Europe have been made including AMADEUS for developing dexterous arms for underwater manipulation; GREX – coordination and control of cooperating heterogeneous unmanned systems in uncertain environments; CO-3AUVs – cognitive cooperative control for AUVs; FREESUBNET – a Marie Curie research training network on marine robotics; and TRIDENT that developed Girona 500 I-AUV for autonomous underwater intervention tasks.

26. Flying Robots

Stefan Leutenegger, Christoph Hürzeler, Amanda K. Stowers, Kostas Alexis, Markus W. Achtelik, David Lentink, Paul Y. Oh, Roland Siegwart

Unmanned aircraft systems (UASs) have drawn increasing attention recently, owing to advancements in related research, technology, and applications. While having been deployed successfully in military scenarios for decades, civil use cases have lately been tackled by the robotics research community.

This chapter overviews the core elements of this highly interdisciplinary field; the reader is guided through the design process of aerial robots for various applications starting with a qualitative characterization of different types of UAS. Design and modeling are closely related, forming a typically iterative process of drafting and analyzing the related properties. Therefore, we overview aerodynamics and dynamics, as well as their application to fixed-wing, rotary-wing, and flapping-wing UAS, including related analytical tools and practical guidelines. Respecting use-case-specific requirements and core autonomous robot demands, we finally provide guidelines to related system integration challenges.

26.1 Background and History

The field of *aerial robotics* encompasses a very broad class of flying machines that nowadays often possess the perception capabilities and decisional autonomy to accomplish complex tasks without the need for any direct human intervention. Historically and within the aerospace jargon, robotic flying machines are commonly referred to as *unmanned aerial vehicles* (UAVs), while the entire infrastructures, systems and human-machine interfaces required for autonomous operation are often called *unmanned aerial systems* (UAS). Aerial robotic technologies are currently on the cutting edge of aerospace and robotic research. Breakthrough contributions take place in various fields such as design, estimation [26.1], perception [26.2], control [26.3], and planning [26.4], paving the way for a historical change on how flying systems are operated and what application challenges they fulfill.

As a class of systems, aerial robots have their roots in the first guided missiles; however, nowadays they refer to a wide variety of advanced intelligent systems. According to the American Institute of Aeronautics and Astronautics (AIAA) [26.5], a UAV is defined as

an aircraft which is designed or modified, not to carry a human pilot and is operated through electronic input initiated by the flight controller or by an onboard autonomous flight management control system that does not require flight controller intervention.

As is generally the case in robotics, aerial robots tend to become more and more complex systems as a result of the effort to achieve advanced decision making and planning capabilities based on its on-board perception of the environment and a set of relatively abstract mission goals.

Aerial robots possess the unique capability to gently fly over terrain that other robots struggle to roll or crawl over. The price to be paid is related with the advanced challenges in terms of system design, propulsion, perception, control, and navigation. Autonomous flight requires handling of all six degrees of freedom and advanced cognition capabilities within challenging environments. In that sense, perception and navigation complexity drastically increase, while payload and available power consumption for processing tends to be limited, especially as scale decreases. Essentially, the design of aerial robots requires increased attention and thorough selection, or even combination, of one or more existing or new flying concepts, electronic components and algorithms. The design engineer has to assess specific optimization challenges and trade-offs

as important desired goals like decreased weight and modularity typically contradict each other.

26.1.1 A Glimpse of History

Aerial robotics is a field of active research and promising perspectives, yet it already accumulates more than a century of developments. Figure 26.1 depicts some historical as well as recent examples of UAVs in the military and civilian sector. Starting as conceptual designs in the context of the human efforts to develop flying machines, aerial robots soon proved their extensive potential and have already created their own legacy. As was also the case for manned aviation, aerial robotic technologies accelerated within the framework of the 20th century world conflicts. Within World War I, Hewitt–Sperry developed an automatic plane that acted as a flying torpedo, carrying onboard intelligence to autonomously sustain flight over long periods of time. This page-turning success was achieved through the integration of (Sperry's self-made) gyroscopes which were then mechanically connected to the control surfaces and therefore established the necessary feedback control loop. During World War II, the German armed forces deployed one of the first successful cruise missiles, the V-1. Despite the fact that V-1 had limited success rate it did incorporate most of the elementary components, estimation algorithms and control loops that can allow autonomous navigation and reference tracking. Military applications kept being, and still are, the main driving force of aerial robotics research and the newest developments in the area change and shape the modern warfare. With the introduction of global positioning systems (GPSs), aerial robots managed to achieve the first completely autonomous surveillance missions. As information and intelligence gathering became one of the most important aspects of the world's open or silent conflicts, military research around the 1970s led to systems equipped with cameras and other sensory systems, giving birth to the UAV prototype the way we know it today. However, civil applications are currently emerging at a very fast pace and the majority of market predictions converge to the conclusion that this area will take dominant characteristics, and most importantly, will become an equally important – if not more – innovation drive.

Within this framework, the advancements in the field of microprocessors, miniaturized sensing, as well as actuator efficiency and downscaling greatly accelerated the field of aerial robots and paved the way for the great achievements we observe today. Aerial robots have advanced to a state in which sophisticated sensor

Fig. 26.1 A glimpse on the UAS history through some examples starting from the Hewitt–Sperry Automatic Airplane (1917), the V-1 flying bomb (1944), and the Lockheed D-21 (1962) until the recent examples of military (Predator, Robocopter, nEuron) and civilian (AtlantikSolar, Firefly, Apid 60) aerial robots

modules for onboard state estimation and environmental perception, powerful embedded processors running sophisticated navigation algorithms, potentially several

communication interfaces, as well as high-end-mission-oriented payloads that enable the execution of challenging tasks, can be tightly integrated.

26.2 Characteristics of Aerial Robotics

This section aims to provide an overview of the key characteristic features and properties of different aerial robotic configurations as well as a classification based on the key advantages and limitations of some of the most common flying concepts found in unmanned aviation.

26.2.1 Aerial Robots Classification

Compared to the categorization of manned aviation, aerial robots classification is more complex, as the term currently refers to a very wide variety of systems of different scale, mechanical configuration, and actuation principles. In their vast majority, aerial robots correspond, in one way or another, to miniaturized versions of manned aircraft designs. Relatively classical fixed-wing unmanned aerial systems (FW-UAS) de-

signs and rotary-wing unmanned aerial systems (RW-UAS) such as those shown in Fig. 26.2 are common vehicle configurations one may encounter in most applications, including those of surveillance, monitoring, inspection, mapping, or payload transportation. However, even within these relatively traditional concepts, several design aspects differ from those chosen for manned systems. This reflects the fact that for different scales, the variation of the physical properties behavior, along with the search for optimized designs, will naturally lead to modified and novel design considerations. This is further triggered by the fact that the absence of a pilot on-board unlocks a wide set of engineering choices, typically out of question or even forbidden in manned aviation. As expected for a multitude of engineering reasons, large UAS tend to follow design concepts closer to – while at smaller scale to classi-

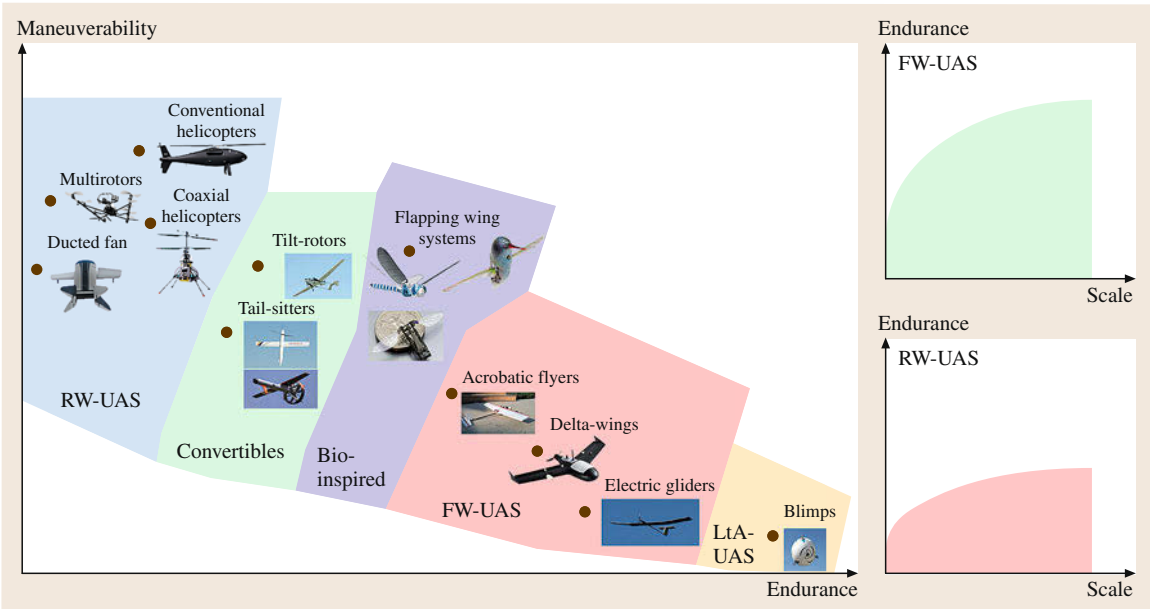

Fig. 26.2 Classification of aerial robotics based on their endurance and maneuverability properties. Also note the significant effect of scale which highlights that comparisons should be done on similar scales

cal designs while as scale decreases innovation – at the level of the flying principle – becomes more and more intense.

Apart from *lighter-than-air* systems (**LtA-UAS**), **FW-UAS** tend to be the most power efficient flying principle, while **RW-UAS** are tailored to increased maneuverability as well as the ability of stationary vertical flight (*hovering*). This general classification (also valid for manned aviation) is then further complicated with the relatively large class of convertible designs (such as tilt-rotors or cruise-flight-enabled ducted fans). This first attempt for aerial robots classification has then to be further augmented to account for the biologically inspired concepts, and especially the emerging field of flapping-wing UAS (**FI-UAS**). Figure 26.2 provides an abstract – yet incomplete – overview of the vehicle classes one may encounter in most of the application fields. As shown, a large diversity is observed as a result of the engineering efforts to propose designs with optimized endurance, agility, controllability, or even simplicity in a very wide scale range. In the following subsections, a brief overview on how the main aerodynamic forces and effects depend on the design scale of an aerial vehicle are provided.

26.2.2 The Effect of Scale

The understanding of how aerial vehicles manage to remain airborne, provides a useful insight into the effect of scale, and how different dimensioning has

a huge impact on the efficiency of every flying machine. Table 26.1 provides an overview of the formulas expressing the lift force, as well as the drag forces that govern the flight of the most common UAS configurations. More detailed definitions on the aerodynamic forces can be found on the subsequent sections.

Within these equations, ρ is the density of the air while the remaining parameters are specific to the vehicle configuration. For **FW-UAS**, c_L and c_D represent the wing lift and drag coefficients, respectively, A is the wing area, and V_t denotes the airspeed. For the case of **RW-UAS**, c_T and c_Q denote the rotor thrust and drag coefficients, (πR^2) is the rotor disk area, Ω is the angular velocity of the rotor, and R is the rotor disk radius. Finally, for **LtA-UAS**, V^{LtA} is the volume of the blimp, c_D^{LtA} is the drag coefficient depending on the blimp shape, V_t is the blimp's airspeed, A^{LtA} is the blimp surface in the direction of motion and ρ_{gas} is the filling gas density. Figure 26.3 illustrates

Table 26.1 Formulas of the main aerodynamic forces and moments for common UAS configurations. **FW** stands for *fixed-wing* UAS, **RW** for *rotary-wing*, and **LtA** for *lighter-than-air*

UAS	Lift/Thrust	Drag force/Moment
FW	$L = \frac{1}{2} c_L \rho A V_t^2$	$D = \frac{1}{2} c_D \rho A V_t^2$
RW	$T = c_T \rho (\pi R^2) (R \Omega)^2$	$Q = c_Q \rho (\pi R^2) (R \Omega)^2 R$
LtA	$L_s = -g V^{LtA} (\rho_{gas} - \rho)$	$D = \frac{1}{2} c_D^{LtA} \rho A^{LtA} V_t^2$

Fig. 26.3a–c Main aerodynamic forces applied on (a) fixed-wing, (b) rotary-wing, and (c) lighter-than-air systems. these forces on the body of the relevant aerial vehicle configurations.

Derivation of *scaling laws* starts with the observation of the lift and drag forces and how these are functions of scale-dependent parameters such as the area of the wing or the rotor radius. Proper dimensioning is essentially a very complex procedure where a multitude of factors has to be taken into account. Among others, one has to account for the issues of aerodynamics efficiency, availability of propulsion systems at a given scale, the technologies they employ (e.g., electric motors, jet engines) as well as the simplicity and robustness of the corresponding mechanical configuration. In the following, scaling laws and relevant design guidelines for fixed-wing, rotary-wing, and lighter-than-air systems are provided. Only a brief overview is provided for the case of flapping-wing systems, as the effect of scale on such UAS configurations is separately discussed within Sect. 26.6.

FW-UAS

Scaling laws express the dominant role of size and scale for a given vehicle configuration. In the case of fixed-wing systems, the wing loading, defined as the ratio of the weight (W) versus the wing area A , is the key parameter one has to focus to get some first insight on the role of scale. The Tennekes diagram shown in Fig. 26.4 provides a visual interpretation of this fact [26.6]. Working around the point that the lift force exactly counteracts the weight, the indicated trend line was derived using the following formulas [26.7]

$$\begin{aligned}\frac{W}{A} &= \sqrt[3]{W} 47, \\ \frac{W}{A} &= \frac{1}{2} c_L \rho V_t^2, \\ A &= b_w c_w, \end{aligned} \quad (26.1)$$

where V_t is the airspeed, W is the weight, A is the wing area, b_w is the wing span, and c_w is the wing chord. These equations express the role of the lifting properties

of the airfoil and airspeed against the ratio of the weight of the flying body and its wing area. For this analysis, a fixed aspect ratio ($\Lambda = b_w/c_w$) is assumed for all sizes of aircraft. Although such a simple analysis does not account for the details of the fluid dynamics environment between the different aircraft sizes, it is known that smaller aircrafts are typically built with lower aspect ratios, and that the difference in aspect ratio over existing aircraft within the size range of interest is significant.

RW-UAS

For the case of rotorcraft configurations, similar scaling laws regarding the vehicle efficiency may be derived. It is important to highlight however that especially for rotorcrafts, working with scaling laws demands that one has to simultaneously focus on both efficiency and dynamic response in order to avoid undesired effects in the vehicle flight dynamics such as unstable oscillations. Regarding the power efficiency, let power loading (PL) be defined as T/P , where P corresponds to the ideal power. As the induced ideal power to hover is given by $P = T v_h$, the *ideal power loading* will be inversely proportional to the induced velocity at the rotor disk v_i

$$v_h = v_i \Rightarrow \sqrt{\frac{T}{2\rho(\pi R^2)}} = \frac{P}{T} = (PL)^{-1}. \quad (26.2)$$

Observing Fig. 26.5, it is shown that the ratio T/P decreases quickly with increasing disk loading. Therefore, configurations with proportionally smaller rotors against their mass will tend to be less efficient in hovering flight; that is, the rotor will require proportionally more power to generate the required amount of thrust. It is also to be noted, however, that calculation of the actual power loading and rotor efficiency requires the consideration of viscous losses.

From the above brief analysis, we concluded that in general the tendency to increase the rotor dimension favors efficiency. However, this is not the only scaling law one has to consider. Rotorcrafts are particularly com-

Fig. 26.4 Tennekes size trend relating wing loading and cruise speed to weight for insects, birds, and manned aircraft

plex dynamic systems and scaling considerations also have to focus on dynamic aspects of their flight. A more concrete analysis may take place using Froude or Mach scaling models. Let N denote the length scale between two vehicles, R_m the rotor radius of the model vehicle, and R_p the rotor radius of the prototype vehicle: thus, a scale factor N denotes a helicopter $1/N$ times the size of its prototype. Table 26.2 summarizes the Froude and Mach scaling laws that account for the role of scale in a set of significant parameters namely the length of the model and the prototype L_m , L_p , the dominant time constants t_m , t_p of the inner-loop characteristic response,

the characteristic velocities V_m , V_p , the weight values W_m , W_p , the expected moments of inertia I_m , I_p , and the response-dominant frequencies ω_m , ω_p .

These, slightly more advanced scaling laws, further provide the opportunity to assess the aspects of main rotor performance, and more specifically the expected thrust margin. Traditional manned helicopters have small thrust margins in hover, typically 5–10% while miniaturized vehicles often present very high values. Mach models predict in general faster rotor speeds as compared to Froude scaled models, which consequently leads to a lower expected thrust coefficient. The

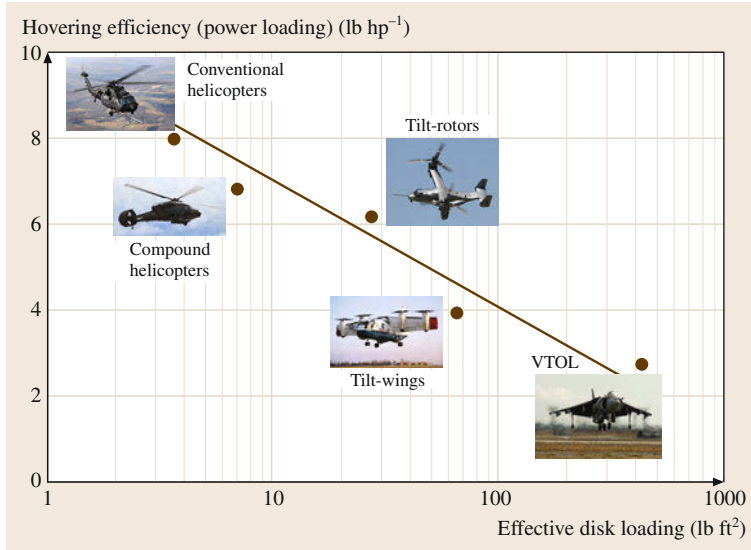

Fig. 26.5 Hovering efficiency versus disk loading for a range of vertical lift aircraft

Table 26.2 Scaling laws for conventional helicopters

Dimension	Froude	Mach
Length	$L_m = L_p/N$	$L_m = L_p/N$
Time constant	$t_m = t_p/\sqrt{N}$	$t_m = t_p/N$
Speed	$V_m = V_p/\sqrt{N}$	$V_m = V_p$
Weight	$W_m = W_p/N^3$	$W_m = W_p/N^3$
Inertia mat.	$I_m = I_p/N^5$	$I_m = I_p/N^5$
Frequency	$\omega_m = \omega_p\sqrt{N}$	$\omega_m = \omega_p N$

thrust coefficient reflects the lift loading of the rotor. For a given, single rotor configuration, the maximum thrust is provided by the following expression

$$T_{\max} = (c_T/\sigma)_{\max} \rho (\pi R^2) (\Omega R)^2, \quad (26.3)$$

where σ represents the blade solidity (Sect. 26.3.4). This relation gives a maximum thrust that scales as $T_{\max} \propto 1/N^3$ for a Froude model and as $T_{\max} \propto 1/N^2$ for a Mach model. Once divided by the vehicle weight which scales as $W \propto 1/N^3$, it is deduced that Froude models present a similar thrust-to-weight ratio. On the contrary, for a Mach model, there is an increasing expected maximum thrust-to-weight: $(T/W)_{\max} \propto N$. Using these formulas, researchers in [26.8] calculated

the scaling parameters for several conventional helicopters that provide intuitive insight on how scaling laws work.

LtA-UAS

For the case of lighter-than-air vehicles simple scaling laws regarding the efficiency of the system hold. Considering the example of a spherical blimp, it is directly deduced that the lift force scales with the cubic power of the radius. On the other hand, its mass, which depends on the surface, scales with the square power of the radius and also does the drag force. This essentially indicates that larger blimps will tend to have a higher maximum lift to weight and lift-against-drag force ratios.

FI-UAS

Analysis of the scaling laws for flapping wing systems requires a different treatment, as the flight modality changes while the robot operates in *hover* mode or navigates in *forward flight*. Furthermore, the lift and drag coefficients are dependent on the airfoil characteristics of the wing and also on the flapping frequency, a fact that further increases the complexity of the analysis on the effect of scale. Section 26.6 provides insight on how to deal with this challenging issue so that proper flapping wing systems design is achieved.

26.3 Basics of Aerodynamics and Flight Mechanics

Assembling an analytic representation of a UAS involves the derivation of approximative expressions for the aerodynamic forces, accounting for the actuator dy-

namics and appending the resulting effect to the vehicle body equations of motion. The goal of this section is to provide the necessary insight and understanding of

Fig. 26.6 Variation of (a) air temperature, (b) pressure, and (c) density with altitude in the lower part of the International Standard Atmosphere. The tropopause, above which the temperature is not further decreasing, corresponds to the red dashed line. It constitutes the upper limit of common weather phenomena

the underlying mechanisms and physical phenomena along with the derivation of the formulae for the most dominant effects one has to account for with any UAS configuration.

26.3.1 Properties of the Atmosphere

Assessing flow properties forms the basis for any further qualitative or quantitative aerodynamic analysis relevant for aircraft design, modeling and control. The international standard atmosphere (ISA) [26.9] provides a reference for the average main air characteristics as a function of altitude. Figure 26.6 shows the evolution of air temperature T_{air} , pressure p , and density ρ . These parameters largely affect the Reynolds number Re , which can be interpreted as the influence of inertial forces as compared to viscous forces of a flow, as well as the Mach number Ma representing the ratio of airspeed versus speed of sound.

It is noteworthy that the above parameters may be brought into relationship by the ideal gas law

$$p = \rho R T_{\text{air}}, \quad (26.4)$$

with $R = 286.97 \text{ m}^2/\text{s}^2/^\circ\text{K}$ denoting the ideal gas constant of air.

Fig. 26.7 Characteristics of a 2-D flow around an airfoil 1 – Free stream velocity field, 2 – Streamline, 3 – Stagnation point, 4 – yLaminar boundary layer, 5 – Overpressure, 6 – ySuction, 7 – Transition point, 8 – Turbulent boundary layer, 9 – Separation point, 10 – Separated flow

In contrast to *aerodynamics*, where forces, first and foremost lift, is generated by motion of an object through the air, the *aerostatic* lift force is formed solely by static properties of an object. It forms the basis of operation for a balloon or blimp.

According to Archimedes' principle, the aerostatic lift L_{stat} pointing upward, amounts to

$$L_{\text{stat}} = \rho V g - m g, \quad (26.5)$$

where g stands for the Earth gravitational acceleration, V for the volume of the object, and m for its mass. To state an example, consider a helium balloon of spherical shape with a diameter amounting to 1 m in the lower atmosphere. Neglecting its hull weight (thus with $m = \rho_{\text{helium}} V$), it will generate an aerostatic lift force of 5.4 N, representing an upper bound for any kind of total design mass including payload. Increasing the diameter of said sphere to 1.5 m has the huge effect of increasing lift to 18.1 N.

26.3.2 General Fluid Dynamics and 2-D Flow around Airfoils

A general airflow around an aircraft is three-dimensional, unsteady, and may be turbulent, even interacting with a nonrigid structure. In this setting, computations are almost intractable. We will thus rely on certain simplifications in order to allow simpler calculations and notably enhancing the understanding of a flow field together with resulting forces and moments. In both airplane and rotorcraft aerodynamics, the assumption of a locally two-dimensional (2-D) flow can be very helpful to serve as a starting point for more advanced computation.

Before diving into a formal treatment, the example in Fig. 26.7 depicts some characteristic elements of 2-D flow around an airfoil.

Notice that the pressure distribution on the airfoil contour is induced by the flow field, making the most

significant contribution to the aerodynamic force and moment. However, also viscous effects yield a typically unwanted share in the overall force (and moment) in the form of shear stress transmitted to the surface. The elements overviewed in Fig. 26.7 will now be explained in the following paragraphs.

Finite Control Volume Analysis: Mass and Momentum Conservation

Consider a finite control volume B bounded by the surface S with normal \mathbf{n} , which may contain a body or airfoil, depending on the context. For convenience, parts of the boundaries are often chosen to be streamlines (in 2-D) or stream surfaces (in 3-D). For this volume, the *conservation of mass* must be fulfilled

$$\iint_S \rho \mathbf{v} \cdot \mathbf{n} dS, \quad (26.6)$$

where \mathbf{n} denotes the fluid velocity vector.

From classical Newtonian mechanics, we can furthermore postulate the applicability of *conservation of linear and angular momentum*

$$\begin{aligned} \mathbf{F}_{\text{tot}} = & \iint_S \rho \mathbf{v} (\mathbf{v} \cdot \mathbf{n}) dS + \iint_S p \mathbf{n} dS \\ & + \frac{\partial}{\partial t} \iiint_B \rho \mathbf{v} dB, \end{aligned} \quad (26.7)$$

$$\begin{aligned} \mathbf{M}_{\text{tot}} = & \iint_S \rho (\mathbf{v} \times \mathbf{r}) (\mathbf{v} \cdot \mathbf{n}) dS \\ & + \frac{\partial}{\partial t} \iiint_B \rho (\mathbf{v} \times \mathbf{r}) dB, \end{aligned} \quad (26.8)$$

where \mathbf{r} denotes the position vector.

Differential Volume Analysis: Euler and Bernoulli Equations

When applied to a differential volume and assuming inviscid flow, (26.7) can be used to derive *Euler's equation*

$$\rho \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v} + \nabla p = \mathbf{0}. \quad (26.9)$$

This equation forms the basis of many finite-element-based numerical tools neglecting viscous effects outside the boundary layer. Such methods employ potential flow theory along with some boundary layer analysis module; free example tools are JavaFoil [26.10]

and xfoil [26.11] for 2-D flow computation as well as XFLR [26.12] allowing also 3-D flow extensions.

When applying (26.9) along a streamline and under the assumption that the flow is incompressible (a fair assumption for low-speed aerodynamics up to $\text{Ma} = 0.3$), *Bernoulli's equation* relating speed (V_t) and pressure can be formulated

$$\rho \frac{V_t^2}{2} + \rho gh + p = \text{const}, \quad (26.10)$$

where g denotes gravitational acceleration and h the elevation – the aerostatic pressure component ρgh can often be neglected due to small elevation changes along a streamline.

Viscous Effects and the Boundary Layer

While it is often a valid approximation to neglect viscous effects far enough from the body surfaces, they have to be considered within the boundary layer, where the fluid is slowed down to meet the speed of the surface. The friction shear stress τ_w transmitted to the surface is characterized by the gradient of the flow speed perpendicular to the surface

$$\tau_w = \mu \frac{dU}{dn}, \quad (26.11)$$

where μ denotes the dynamic viscosity of the fluid, U stands for the airspeed parallel to the surface, and n for the coordinate along the surface normal \mathbf{n} . This tangential fluid velocity gradient in the boundary layer is visualized qualitatively in Fig. 26.7.

The boundary layer will be laminar around the nose, with the fluid moving parallel to the surface. At some point (at a critical local Reynolds number), however, influenced by disturbances such as surface roughness, a transition to a turbulent boundary layer will occur: it is characterized by stochastic fluctuations, significantly thicker and producing substantially more friction than before the transition.

Fig. 26.8 Decomposition of the aerodynamic force by a 2-D flow around an airfoil: the section lift dL denotes the component perpendicular to the far-field inflow, and drag dD the one parallel to it

Fig. 26.9a–c SA7036 low-speed airfoil lift (a), drag (b), and moment (c) polars for various Reynolds numbers calculated by Javafoil

Section Lift, Drag, and Moment Representation with Dimensionless Coefficients

Historically and for practical reasons, the aerodynamic force is split into a component perpendicular to the inflow direction called *lift*, and a second one parallel to the inflow called *drag*. We write **2-D** lift, drag, and moment as infinitesimal quantities dL , dD , and dM , respectively, as opposed to L , D , and M designating physical forces of a whole airplane. Figure 26.8 visualizes these quantities. Furthermore, we define the angle of attack α as the angle between inflow direction and the chord line of length c connecting airfoil leading edge and trailing edge. Note that force and moment are reduced to the point at $0.25c$, i. e., one quarter of the chord behind the leading edge.

Dimension analysis suggests the formulation of aerodynamic forces and moments in terms of section lift, drag, and moment coefficients c_l , c_d , and c_m

$$dL = \frac{1}{2} \rho V_t^2 c_l c dy, \quad (26.12)$$

$$dD = \frac{1}{2} \rho V_t^2 c_d c dy, \quad (26.13)$$

$$dM = \frac{1}{2} \rho V_t^2 c_m c^2 dy, \quad (26.14)$$

where V_t stands for the inflow speed and dy denotes an infinitesimal length element perpendicular to the **2-D** flow (which can be interpreted as a length element into span-wise direction of an infinitely long wing).

These coefficients largely depend on the angle of attack α ; but furthermore, the Reynolds and Mach num-

bers significantly influence them as well. The angle of attack dependences are typically given in the form of section lift, drag and moment polars, an example of which is provided in Fig. 26.9. Note that the drag component is originating both from viscous skin friction as well as form drag, caused by an asymmetric pressure distribution due to boundary layer development and separation. The lift curve shows its characteristic linear increase with increasing α for small angles of attack. The maximum and minimum lift values beyond which stall is entered are clearly visible in the lift polar. Note that the aerodynamic performance c_l/c_d of the airfoil generally decreases with smaller Reynolds numbers as expected. The choice of reference point at $0.25c$ typically leads to a mostly constant moment coefficient when varying α , c_l , respectively, as can be seen in Fig. 26.9 as well.

Separation and Stall

At the upper side of the airfoil, the fluid is moving from the under-pressure region toward a higher pressure at the trailing edge; the slower moving fluid in the boundary layer will at some point not be able to follow this adverse pressure gradient, leading to flow separation. As the angle of attack is increased, the separation point suddenly moves far toward the leading edge: this condition is referred to as stall, with the catastrophic consequence of significant loss of lift and increase of drag. Figure 26.10 illustrates the changes in the flow and pressure distribution when varying the angle of attack. Note that the maximum lift and stall conditions are highly influenced by the choice of airfoil, Reynolds number, and Mach number.

26.3.3 Wing Aerodynamics

So far the 2-D flow characteristics around airfoils were treated. This will form the basis for the understanding and computation of lift and thrust forces generated on any type of aircraft; the following treatment of a finite wing serves as an important example of how to include three-dimensional (3-D) flow effects.

Recording lift and drag polars for a finite wing rather than just for its airfoil reveals less lift increase per angle of attack increase, less maximum lift, and higher drag at raised angles of attack. These observations are related to the concept of *induced flow* to be treated in the following.

Vortex System of a Wing

As a direct consequence of lift, we observe a downward flow deflection across an airfoil. This is intuitively explained with conservation of linear momentum as stated in (26.7). Assuming an inviscid and incompressible fluid, the flow may be modeled with potential field theory [26.13], where the velocity vector field is defined as the gradient of a scalar function. This concept allows for the insertion of singularities into a free stream, such as sources, sinks, and vortices. Figure 26.11 shows a first approximation using a single vortex – conceptually illustrating the flow characteristics around a simplified wing. The vortex system consists of the bound vortex and tip vortices; note that the vortex will in theory have to be closed to a ring by a starting vortex. In practice, i.e., in the presence of friction, the vortices will of course decay over time. Figure 26.12 illustrates the existence of tip vortices trailing an airplane wing.

The vortices induce a downwash area behind the wing; nevertheless, the trailing vortices will also induce some downward flow at the wing.

Induced Drag

With the simplified concept of the vortices around a wing in mind, we conclude that the wing lift induces downward flow, thus reducing the effective angle of attack when looking at the 2-D-flow of a wing cross-section. Figure 26.13 illustrates this reduction of the angle of attack from α_f (free stream) to α_e (effective) by the induced angle α_i that is caused by the induced flow component w_i . Note that this reduction of angle of attack is typically resulting in a smaller lift. Furthermore, when decomposing the lift into components parallel and perpendicular to the free stream velocity, it becomes apparent that a part dD_i of the lift results parallel to the effective inflow, thus will contribute to the overall drag of the wing. The integral of these components is referred to as induced drag. The actual amount of induced drag largely depends on the wing geometry; a variety of

Fig. 26.10a–d Changes in the flow characteristics with increasing angle of attack α . For a small α (a) the example nonsymmetric airfoil will generate some lift. (b) depicts nominal operation. At some α , the maximum lift $c_{l,max}$ is reached (c). Beyond that angle of attack, stall occurs (d)

Fig. 26.11 Simplified representation of the wing vortex system: as a consequence of lift, a bound vortex is formed along with trailing wingtip vortices inducing downwash

approaches have been employed in order to minimize induced drag, the most popular of which are winglets.

Fig. 26.12 Wake vortex study by NASA at Wallops Island: the tip vortices are visualized using colored smoke rising from the ground

Fig. 26.13 Induced drag on a finite wing cross section: the induced downwash w_i causes a reduced effective angle of attack. As a consequence, the lift dL contains a component dD_i parallel to the free stream velocity vector

For an approximately elliptical lift distribution, the induced drag coefficient can be roughly calculated as

$$c_{D,i} = \frac{C_L^2}{\pi e \Lambda}, \quad (26.15)$$

with the aspect ratio Λ and the Oswald efficiency e (deviation from the truly elliptic distribution) amounting from 0.7 to 0.85 for typical configuration.

Lifting Line Method

In the following, we present one example of how to numerically approximate the lift and drag distribution of a wing including induced drag. The lifting line method is a 2.5-D (two-and-a-half-dimensional) approach in which the induced flow is viewed as generated by several discrete horseshoe vortices rather

than just one as introduced qualitatively earlier. Figure 26.14 depicts the geometry and variables involved. Note that the method only provides reliable results, if the assumption holds that spanwise flow is negligible; in particular, spanwise variation of parameters such as chord length and twist is supposed to be rather small. The Kutta–Joukowski theorem relates circulation and lift; applied to a discrete wing segment, we obtain

$$\Gamma_k = \frac{1}{2} c_k c_{l,k} (\alpha_{\text{eff}}) V_t, \quad (26.16)$$

with the segment (index k) circulation Γ_k , the local chord length c_k , and the local airfoil lift coefficient $c_{l,k}$. The lift coefficient depends on the effective angle of attack: $\alpha_e = \alpha_f - \alpha_i$. The induced downwash at position \mathbf{m}_k is obtained by adding the induced speeds of all the individual vortices according to Biot–Savart

$$w_{i,k} = \sum_{j=1}^{n+1} \frac{\Gamma_j \mathbf{e}_V}{4\pi \|(\mathbf{p}_j - \mathbf{m}_k) \times \mathbf{e}_V\|} \times \left(1 + \frac{(\mathbf{p}_j - \mathbf{m}_k) \cdot \mathbf{e}_V}{\|(\mathbf{p}_j - \mathbf{m}_k)\|} \right), \quad (26.17)$$

where \mathbf{e}_V stands for the (unit) direction of flight. At \mathbf{m}_k , the induced angle of attack is calculated as

$$\alpha_{i,k} = \arctan \frac{w_{i,k}}{V_t} \approx \frac{w_{i,k}}{V_t}. \quad (26.18)$$

Together with the respective 2-D polar data, the above relations allow calculating the lift, drag, and moment distribution (with respect to the free inflow direction \mathbf{e}_V) from a known circulation distribution, and can be summed and reduced to, e.g., the center of mass of a whole airplane. Note that the section lift coefficient is often approximated linearly as $c_l(\alpha) \approx c_{l,0} + c_{l,\alpha} \alpha$, which allows for a direct solution when applying (26.16) and (26.17). More accurate results, in particular in the domain near maximum lift, however, are obtained by using the nonlinear lift polar. In this case, a standard iterative numeric solver may be used. Furthermore, airfoil data with deflected control surfaces can be included, allowing to calculate control moments (and forces).

Note that the above method is just one example of numerically solving for the wing characteristics knowing the 2-D airfoil properties (polars) – well-suited for low-speed medium to high aspect ratio wings. For an overview on alternatives, the reader is referred to, e.g., [26.13].

Fig. 26.14 k horse shoe vortices with circulation Γ_k placed on the wing to model the induced flow. The lifting line is imagined through the quarter-chord ($c_k/4$) locations. Vortex threads with strength $\Delta\Gamma_k$ are leaving the wing at the points p_k along the inflow and induce downwash at the locations m_k

26.3.4 Performance of Rotors and Propellers

The propulsion mechanism found on many robotic aerial vehicles is commonly a specific configuration of propellers or rotors. In the case of a robotic airplane, forward facing propellers produce thrust forces compensating drag in forward flight. In case of a tail sitter or multicopter UAV, the propellers may be facing up (or down) and produce the main lift component compensating the vehicle's weight allowing it to hover in the air. Similarly, the more classic helicopter-type configurations (single rotor with tail rotor, coaxial rotor, tandem rotor, etc.), use rotors to generate the required thrust force to fly.

In order to decide on a suitable rotor or propeller geometry and to define requirements for the UAV motor drives, models must be available which allow for an assessment of the thrust and torque characteristics of a particular rotor or propeller. For this purpose, the blade element momentum theory (BEMT) has found widespread use, as it often provides a prediction accuracy which is acceptable for the UAV design process (despite its simplicity).

Blade Element Momentum Theory

One of the basic difficulties in aerodynamic rotor and propeller studies is the prediction of the induced inflow velocities discussed in Sect. 26.3.3. BEMT addresses this problem by combining two simple modeling approaches, namely momentum theory (MT) and blade element theory (BET) which individually cannot directly resolve this issue in an accurate manner [26.14].

The basic idea of momentum theory is to consider the revolving propeller or rotor as a propulsion disk which produces a thrust force by accelerating the surrounding (incompressible) air mass passing through it. A boundary volume is defined encapsulating the

propulsion disc. Subsequently, the laws of mass, momentum and power conservation are formulated across the boundaries of the defined control volume. The concept of this propulsion disk as well as the corresponding control volume are visualized in Fig. 26.15.

From this simplistic model, two main conclusions may be drawn. First and foremost, it is possible to establish a relation between the induced velocity v_i at the propulsion disk and the produced thrust force T . In normalized form, it can be expressed as

$$c_T = 2\lambda_i(\lambda_i + \lambda_\infty). \quad (26.19)$$

To simplify notation, the external airflow velocity v_∞ as well as the induced velocity v_i have been normalized with the rotor or propeller tip speed ΩR

$$\lambda_i = \frac{v_i}{\Omega R}, \quad \lambda_\infty = \frac{v_\infty}{\Omega R}, \quad (26.20)$$

and the nondimensional thrust coefficient c_T is defined as

$$c_T = \frac{T}{\rho(\pi R^2)(\Omega R)^2}. \quad (26.21)$$

Fig. 26.15 (a) Side view on the slipstream control volume encompassing the MT propulsion disc. (b) Top view on MT propulsion disk with incremental annular section and root cutout

The parameter ρ corresponds to the density of air, R to the rotor or propeller radius, and Ω to the rotor or propeller angular speed.

In case of a robotic airplane, the velocity v_∞ at the start of the control volume corresponds to the body forward flight velocity V_i and in case of a rotorcraft configuration to the body climb respectively descent rate w .

Similarly, an incremental expression for the thrust coefficient may be found from MT by evaluating the mass, moment, and power conservation laws over an annular ring of the defined control volume only. The corresponding expression can be found as

$$dC_T^{MT} = 4\lambda_i(\lambda_i + \lambda_\infty)\bar{r}d\bar{r}, \quad (26.22)$$

where $\bar{r} = \frac{r}{R}$ and $d\bar{r} = \frac{dr}{R}$ are the normalized radial location and the radial increment of the propulsion disk annulus.

Another relevant conclusion that may be drawn from MT is that ideally, the induced component v_i of the slipstream velocity at the propulsion disk will accelerate to two times its initial value before leaving the control volume. In consequence to this acceleration of the flow field, the radial slipstream boundary will (in the ideal case) contract to half the propulsion disk area at the end of the control volume.

For the BET approach, the modeling process starts by investigating the aerodynamic lift and drag forces dL and dD on an individual rotor or propeller blade revolving around its shaft. These lift and drag forces produced by each airfoil segment depicted in Fig. 26.16, contribute to the total thrust and torque increments dT and

dQ of the respective rotor or propeller annular section. The corresponding relation can be established as

$$dT = N_b(dL - \Phi dD) \approx N_b dL, \quad (26.23)$$

$$dQ = N_b r(dD + \Phi dL). \quad (26.24)$$

In this context, N_b represents the number of rotor or propeller blades and Φ corresponds to the local inflow angle which is assumed to remain small. Under this assumption, the inflow angle Φ can be directly derived as the ratio between the local perpendicular inflow velocity $U_P \approx v_i + v_\infty$ and the tangential velocity $U_T \approx \Omega r$ visualized in Fig. 26.16b. Additionally, the assumption introduced in (26.23) is justified by the fact that at low angles of attack α , the drag forces dD are at least one order of magnitude smaller than the corresponding lift forces dL .

Based on (26.23) and the definition of the lift increment (26.12), the local thrust coefficient at each radial blade station r may be derived as

$$dC_T^{BET} = \frac{1}{2} \sigma c_l \bar{r}^2 d\bar{r}, \quad \text{with} \quad \sigma = \frac{N_b c}{\pi R}. \quad (26.25)$$

The parameter c corresponds to the local blade chord and σ is the so-called rotor or propeller *solidity*. The solidity is a rough metric representing how much of a propulsion disk is covered by rotor or propeller blades. The aerodynamic parameter $c_l = c_l(\alpha, Re, Ma)$ corresponds to the airfoil lift coefficient in function of the local angle of attack α and the local Reynolds and Mach numbers Re and Ma .

Accordingly, as established in (26.25), the thrust produced by a rotor or propeller strongly depends on the angle of attack α , which itself is a function of the local airfoil pitch angle θ and the inflow angle Φ

$$\alpha = \theta - \Phi \approx \theta - \frac{U_P}{U_T}. \quad (26.26)$$

In conclusion, MT as well as BET are capable of establishing a meaningful relation between the induced velocities v_i and the resulting thrust force T . However, none of the two theories are capable of accurately predicting rotor or propeller performance as either the radial distribution of the induced velocity or the radial distribution of the thrust coefficient must be known to compute the other.

The basic idea behind BEMT is to combine the thrust expression (26.22) resulting from MT with the thrust expression (26.25) from BET to compute the induced inflow velocity independently of the thrust force. Different BEMT implementations are possible depending on how willing one may be to introduce further assumptions for the section lift coefficient c_l .

Fig. 26.16 (a) Rotor blade revolving around its shaft. (b) Blade element of a revolving rotor blade

Reference [26.14] presents a straightforward approach tailored toward helicopter rotors operating below stall by introducing a linear model for c_l in function of the angle of attack

$$c_l = c_{l1}\alpha + c_{l0}. \quad (26.27)$$

The parameters c_{l0} and c_{l1} can be computed from the lift polars of a particular airfoil geometry for a given range of angles of attack, Reynolds, and Mach numbers. This linear approximation may have limited validity for very low Reynolds numbers and strongly cambered airfoils but is in general acceptable for many typical airfoil geometries found on UAV rotors and propellers. Assembling (26.22) and (26.25) under the assumption (26.27), an algebraic expression of the radial induced inflow distribution can be derived as

$$\lambda_i(r, \lambda_\infty) = \sqrt{A^2 + B - \bar{A}}, \quad (26.28)$$

$$\begin{aligned} A &= \frac{\sigma c_{l1}}{16} - \frac{\lambda_\infty}{2}, \\ \bar{A} &= \frac{\sigma c_{l1}}{16} + \frac{\lambda_\infty}{2}, \\ B &= \frac{\sigma c_{l1}}{8} \theta' \bar{r}. \end{aligned}$$

Note that the lift-curve offset c_{l0} has been absorbed in the virtual pitch angle

$$\theta' = \theta + \frac{c_{l0}}{c_{l1}}, \quad (26.29)$$

to simplify the notation.

Once the approximate radial distribution of inflow velocities has been found, the local rotor or propeller thrust increments (26.25) can be computed. Similarly, the rotor or propeller torque increments derived from BET as

$$dc_Q^{\text{BET}} = dc_{Qi} + dc_{Q0}, \quad (26.30)$$

$$dc_{Qi} = \frac{1}{2} \sigma c_l (\lambda_i + \lambda_\infty) \bar{r}^3 d\bar{r}, \quad (26.31)$$

$$dc_{Q0} = \frac{1}{2} \sigma c_d \bar{r}^3 d\bar{r}, \quad (26.32)$$

can be evaluated based on the inflow distribution given in (26.28). For clarity, the total torque coefficient increment has been separated into its induced component dc_{Qi} originating from the lift forces and its profile component dc_{Q0} due to the drag forces. The aerodynamic drag coefficient $c_d = c_d(\alpha, \text{Re}, \text{Ma})$ can be approximated using a quadratic function in dependency of the angle of attack [26.14]

$$c_d = c_{d2}\alpha^2 + c_{d1}\alpha + c_{d0}. \quad (26.33)$$

The parameters c_{d0} , c_{d1} , and c_{d2} can be computed from the drag polars of the modeled airfoil.

Consequently, the thrust and torque increments may be integrated along the radial direction of the rotor or propeller disk to compute the total thrust and torque coefficients

$$c_T = \int_0^R dc_T^{\text{BET}}, \quad (26.34)$$

$$c_Q = \int_0^R dc_Q^{\text{BET}}. \quad (26.35)$$

These thrust and torque integrals are usually evaluated numerically, as the blade pitch $\theta = \theta(r)$ as well as the blade chord $c = c(r)$ may be nonlinear functions of the radial direction r (blade *twist* and *taper*).

Finally, note that the presented theory may be extended to provide performance estimates under lateral inflow velocities such as in case of a rotorcraft in forward flight and may also be used to assess other types of rotor or propeller configurations such as, e.g., the coaxial rotor. Also note that the prediction accuracy of BET tools can be further improved by accounting for tip-loss effects and the nonlift producing rotor or propeller hub, e.g., using the Prandtl tip-loss function also presented in [26.14] and incorporating a root cutout radius R_0 .

The resulting predictions are generally in good agreement with experimental data – nevertheless, an experimental verification is strongly recommended.

26.3.5 Drag

The sources of drag on aircraft are manifold: historically, the distinction between the lift-dependent *induced drag* and *parasite drag* is made. The latter is further subdivided into *skin friction drag* due to viscous shear stress at the surface, and *form drag*, generated by pressure loss along bodies (i.e., due to boundary layer development or even flow separation). Both these components contribute to the airfoil *profile drag*, i.e., the section drag coefficient c_d introduced before.

On a whole aircraft, many more drag sources are distinguished. For an exhaustive overview, the interested reader is referred to [26.13]. In the following, we will present an overview of drag generated by different typical shapes; note that when simply summing drag of different shapes associated with aircraft parts, the result may be a helpful initial estimate, but can be inaccurate, because of neglecting the interaction of flows resulting in *interference drag*. Depending on the stage of the design process or the desired modeling accuracy, 2.5-D

computations or even full 3-D computational fluid dynamics (CFD) simulations might be necessary to satisfy the needs of aerodynamics calculations.

Skin Friction

The simple but important example of a flat plate of length l in parallel flow is well studied. As introduced in the airfoil theory Sect. 26.3.2, the boundary that develops will be laminar near the leading edge and transitions into a turbulent one, generating more drag, at some point downstream. The friction coefficient is defined as

$$c_f = \frac{2D_f}{\rho V_t^2 S_w}, \tag{26.36}$$

with the wetted surface S_w and the friction drag force D_f . According to [26.13], the coefficients can be approximated by

Laminar : $c_f = 1.328 \text{Re}_l^{-0.5}, \tag{26.37}$

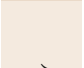

Turbulent : $c_f = 0.455 (\log_{10} \text{Re}_l)^{-2.58}. \tag{26.38}$

Note that the point of transition is depending on the local Reynolds number $\text{Re}_x = \rho V_t x / \mu$, where x denotes the coordinate along the flow from the leading edge of the plate. Depending on the surface roughness and ambient turbulence, the critical (transition) Reynolds number varies; as an average guess for a flat plate, it will be in the order of $\text{Re}_{x,\text{crit}} = 3 \times 10^5$.

Drag Coefficients for Selected Bodies

In the following, drag coefficients for a selection of 2-D and 3-D bodies of rotation are given, obtained

Table 26.3 Bodies the drag coefficients of which are largely Reynolds number independent

	c_D (2-D)		c_D (3-D)	
		1.98		1.18
		2.0		1.0–1.2
		1.3		0.7
		2.0		1.1
		2.2		1.7
		1.4		0.4

from [26.13]. Table 26.3 overviews a category of bodies, the drag coefficients of which are largely indifferent to the Reynolds number, owing to their geometrically defined (sharp edge) flow separation point.

Rounder bodies, most prominently the cylinder in cross-flow or the sphere, however, show a distinctively different behavior quantified in Table 26.4: below a critical Reynolds number $\text{Re}_{\text{crit}} \approx 4 \times 10^5$, the drag coefficient is significantly higher, where separation occurs before boundary layer transition. In contrast, above the critical Reynolds number, the turbulent, more energetic boundary layer separates only further downstream, reducing the wake and thus the amount of form drag.

A third important object category is formed by streamlined and fuselage-like bodies: due to their comparably high skin friction part, the fineness ratio largely influences the drag coefficient (along with the Reynolds number). The fineness is defined as body length divided by body diameter. We introduce a volumetric drag coefficient as $c_{Dm} = 2D / (\rho V_t^2 V_m^{2/3})$ with the body volume V_m . Interestingly, this is minimal and approximately constant at fineness ratios between 4 and 10, which provides a range for optimal sizing of such a body when a certain volume needs to be fitted. The values are given in Table 26.5.

26.3.6 Aircraft Dynamics and Flight Performance Analysis

Sections 26.3.1–26.3.5 shortly presented the basic theory of wings, rotors, and propellers as well as a few tools to assess their respective aerodynamic performance. To develop fully functional UAV platforms, merely evaluating the individual flight mechanisms is a good starting point but generally not sufficient.

Designing high-performance aircraft systems requires a fundamental understanding of how the respective design parameters affect the full flight dynamic response and application-specific capabilities. In order to comprehend how design changes affect an aerial

Table 26.4 Sphere and cylinder drag coefficients

	c_D (2-D)	c_D (3-D)

Fig. 26.17 Coordinate frames with external forces and moments of rotorcraft and fixed-wing UAVs

robotic system, representative models of its flight dynamics are required. Such models must be capable of capturing the dominant system dynamics within the relevant part of the flight envelope. Furthermore, especially in an interdisciplinary field such as robotics, these models must be accessible to the nonaerodynamic expert (the roboticist) and thus need to be simple enough to provide the required insight for the aircraft design process.

As many other types of robots, robotic flight platforms may be treated as a multibody system where a set of interlinked bodies exchanges kinetic and potential energy under the influence of external forces and moments. For aircraft systems it is common to treat the entire aircraft as a single rigid body first, with related body coordinate frame attached, as visualized in Fig. 26.17. Additional dynamics such as for example rotor flapping (as in case of a helicopter system) may be appended to these body dynamics in a subsequent step.

The modeling process thus starts by treating the aircraft system as a rigid body affected by external forces \mathbf{F} and external moments $\boldsymbol{\tau}$. Using the Newton–Euler formalism to derive the aircraft body dynamics, one can directly write down the linear and angular momentum balance for a single rigid body

$$\begin{aligned} m({}^B\dot{\mathbf{v}} + {}^B\boldsymbol{\omega} \times {}^B\mathbf{v}) &= {}^B\mathbf{F}, \\ {}^B\mathbf{I}^B\dot{\boldsymbol{\omega}} + {}^B\boldsymbol{\omega} \times ({}^B\mathbf{I}^B\boldsymbol{\omega}) &= {}^B\boldsymbol{\tau}. \end{aligned} \quad (26.39)$$

For simplicity's sake, (26.39) is usually expressed with respect to a body fixed frame B located in the center of gravity of the aircraft. The velocity vectors ${}^B\mathbf{v} = (u, v, w)^T$ and ${}^B\boldsymbol{\omega} = (p, q, r)^T$ thus represent the aircraft linear and angular velocities with respect to B . The inertial properties of the above body dynamics are defined by the aircraft's total mass m and its second mass moment of inertia ${}^B\mathbf{I}$ also expressed with respect to B and its origin.

The most relevant contribution to the forces ${}^B\mathbf{F}$ and the moments ${}^B\boldsymbol{\tau}$ originates from the aerodynamic flight components such as wings, propellers and rotors. By integrating (26.39) over time one may compute a prediction of the aircraft's dynamic response to these external forces and moments and thus the evolution of its absolute pose. This pose is commonly represented by the position of the vehicle's center of gravity ${}^W\mathbf{r}_B = (x, y, z)^T$ as well as the vehicle's orientation relative to an earth fixed world frame W which is considered inertial. The aircraft orientation is commonly represented using rotation matrices or quaternions. In the case of the rotation matrix representation, the aircraft orientation may be parameterized in three dimensional space by three consecutive rotations with the roll, pitch, and yaw angles $\varphi \in [-\pi, \pi]$, $\theta \in [-\pi/2, \pi/2]$ and $\psi \in [-\pi, \pi]$ as

$${}^W\mathbf{R}_B = \mathbf{R}_Z(\psi)\mathbf{R}_Y(\theta)\mathbf{R}_X(\varphi). \quad (26.40)$$

In this case, relations between the body frame velocities ${}^B\mathbf{v}$ and ${}^B\boldsymbol{\omega}$ and the world frame pose can be expressed as

$$\begin{aligned} {}^W\dot{\mathbf{r}} &= {}^W\mathbf{R}_B {}^B\mathbf{v}, \\ {}^W\dot{\mathbf{R}}_B &= {}^W\mathbf{R}_B [{}^B\boldsymbol{\omega}]^\times, \end{aligned} \quad (26.41)$$

where $[{}^B\boldsymbol{\omega}]^\times$ corresponds to the skew-symmetric matrix of the vector ${}^B\boldsymbol{\omega}$.

In a minimal form, the orientation dynamics can be expressed in terms of roll, pitch, and yaw angles

$$\begin{pmatrix} \dot{\varphi} \\ \dot{\theta} \\ \dot{\psi} \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & \sin \varphi \tan \theta & \cos \varphi \tan \theta \\ 0 & \cos \varphi & -\sin \varphi \\ 0 & \sin \varphi / \cos \theta & \cos \varphi / \cos \theta \end{pmatrix}}_{\mathbf{J}_r} {}^B\boldsymbol{\omega}. \quad (26.42)$$

Note that the Jacobian \mathbf{J}_r becomes singular at the boundaries of $\theta = \pm\pi/2$.

As a singularity-free, but still compact representation of orientation, quaternions may be used. Using the representation ${}^W\mathbf{q}_B = (q_w, q_x, q_y, q_z)^T$ with real part q_w , the rotational kinematics become

$${}^W\dot{\mathbf{q}}_B = \frac{1}{2}\boldsymbol{\Omega}({}^B\boldsymbol{\omega}){}^W\mathbf{q}_B, \quad (26.43)$$

with the matrix $\boldsymbol{\Omega}$ defined as

$$\boldsymbol{\Omega}({}^B\boldsymbol{\omega}) = \begin{pmatrix} 0 & {}^B\boldsymbol{\omega}^T \\ -{}^B\boldsymbol{\omega} & [{}^B\boldsymbol{\omega}]^\times \end{pmatrix}. \quad (26.44)$$

In summary (using quaternions), we thus have the equations of motion

$$\begin{aligned} {}^W\dot{\mathbf{r}} &= {}^W\mathbf{R}_B{}^B\mathbf{v}, \\ {}^W\dot{\mathbf{q}}_B &= \frac{1}{2}\boldsymbol{\Omega}({}^B\boldsymbol{\omega}){}^W\mathbf{q}_B, \\ {}^B\dot{\mathbf{v}} &= \frac{1}{m}{}^B\mathbf{F} - {}^B\boldsymbol{\omega} \times {}^B\mathbf{v}, \\ {}^B\dot{\boldsymbol{\omega}} &= {}^B\mathbf{I}^{-1}[{}^B\boldsymbol{\tau} - {}^B\boldsymbol{\omega} \times ({}^B\mathbf{I}{}^B\boldsymbol{\omega})]. \end{aligned} \quad (26.45)$$

Note that the external forces and moments are related to the system's actuator inputs \mathbf{u} , the vehicle's orientation with respect to W and they typically are also functions of the linear and angular body motion as well as additional dynamics terms, represented here by the vector $\boldsymbol{\varepsilon}_r$,

$${}^B\mathbf{F} = {}^B\mathbf{F}({}^W\mathbf{r}, {}^W\mathbf{q}_B, {}^B\mathbf{v}, {}^B\boldsymbol{\omega}, \boldsymbol{\varepsilon}_r, \mathbf{u}), \quad (26.46)$$

$${}^B\boldsymbol{\tau} = {}^B\boldsymbol{\tau}({}^W\mathbf{r}, {}^W\mathbf{q}_B, {}^B\mathbf{v}, {}^B\boldsymbol{\omega}, \boldsymbol{\varepsilon}_r, \mathbf{u}). \quad (26.47)$$

The additional dynamics $\boldsymbol{\varepsilon}_r$ may account for structural dynamics such as rotor flapping in case of a robotic helicopter or relevant actuator dynamics.

The resulting nonlinear system dynamics can usually be cast into state-space form and represented as

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{u}), \\ \mathbf{x} &= (\mathbf{x}_b, \mathbf{x}_r)^T, \\ \mathbf{u} &= (u_1, \dots, u_N)^T, \end{aligned} \quad (26.48)$$

where the nonlinear functions \mathbf{f} define the rate of change of the aircraft body states \mathbf{x}_b as well as the additional states \mathbf{x}_r affected by the set of N actuator inputs u_1 to u_N .

In order to gain a deeper understanding of how (26.48) is affected by changes of the flight system's geometric, structural, inertial, and aerodynamic parameters, three main problems are commonly of relevance [26.15]:

- The *trim problem* deals with the computation of the set of actuator inputs $\mathbf{u} = \mathbf{u}_0$ under which the nonlinear dynamic system presented in (26.48) remains in a desired trim point $\mathbf{x} = \mathbf{x}_0$ and thus $\mathbf{f}(\mathbf{x}_0, \mathbf{u}_0) = \mathbf{0}$. The most simple example of such a trim point \mathbf{x}_0 is the hover condition for a rotorcraft system where one may want to find the required rotor speed Ω_0 to hover or the steady forward flight condition for a fixed-wing UAV at a forward velocity V_t .
- The topic of *stability* deals with the question of how easily the system (26.48) will deteriorate from a specific trim condition $(\mathbf{x}_0, \mathbf{u}_0)$ under the influence of small disturbances $\Delta\mathbf{x}$ and $\Delta\mathbf{u}$. This investigation commonly involves the linearization of (26.48) according to

$$\begin{aligned} \mathbf{A} &= \left(\frac{\partial \mathbf{f}}{\partial \mathbf{x}} \right)_{\mathbf{x}=\mathbf{x}_0, \mathbf{u}=\mathbf{u}_0}, \\ \mathbf{B} &= \left(\frac{\partial \mathbf{f}}{\partial \mathbf{u}} \right)_{\mathbf{x}=\mathbf{x}_0, \mathbf{u}=\mathbf{u}_0}, \\ \Delta\dot{\mathbf{x}} &= \mathbf{A}\Delta\mathbf{x} + \mathbf{B}\Delta\mathbf{u}, \end{aligned} \quad (26.49)$$

where the eigenvalues and vectors of \mathbf{A} will provide deeper insight into the motion characteristics and stability properties of an aircraft.

- Analyzing the *System Response*

$$\mathbf{x}(t) = \mathbf{x}(0) + \int_0^t \dot{\mathbf{x}} \, dt \quad (26.50)$$

to characteristic inputs such as steps, pulses or specific input frequencies will provide additional information about the flight characteristics of a specific aircraft configuration.

These modeling and analysis concepts commonly find wide applicability for various types of robotic flight configurations and will be discussed in more detail for the specific UAV types presented hereafter.

Actuator Dynamics

Deriving the aerodynamic forces is combined with the dynamic equations of motion in order to assemble a complete model of the flying vehicle. However, as the employed actuators are of naturally limited bandwidth, accurate modeling furthermore requires the integration of the relevant motor or servo dynamics.

Nowadays, motors utilized in small size unmanned systems often belong to the category of brushless direct-current (DC) electric motors (BLDC). BLDCs are synchronous motors powered by a DC electric source via an integrated switching power supply. The equations of motion for a such a system are essentially nonlinear and

rather complex. However, working with small UAS, we may solely focus on the input–output dynamics which can be described with the following transfer function

$$\frac{\Delta\omega(s)}{\Delta Q_m(s)} = \frac{-K_m(1 + \tau_\alpha s)}{(1 + \tau_m s)(1 + \tau_\alpha s) + K_m K_\alpha (K i_{e0})^2}, \quad (26.51)$$

where $\Delta\omega(s)$, $\Delta Q_m(s)$ correspond to the Laplace expressions of the linearized angular velocity and input torque, K_m is the mechanical gain, τ_m represents the mechanical time constant, K_α is the rotor gain, τ_α is the rotor time constant, K depends on electromagnetic properties of the motor and i_{e0} denotes the stator current linearization point [26.16]. Often, a satisfactory speed controller and BLDC dynamics description is obtained as the relation between a reference angular velocity

and the actual output taking the even simpler first-order form

$$\frac{\Delta\omega(s)}{\Delta\omega^r(s)} = \frac{1}{1 + \tau_{mc}s}, \quad (26.52)$$

with the time constant τ_{mc} of the controlled motor.

Accounting for motor dynamics is essential for high-bandwidth control of agile vehicles that highly depend on such actuators (i. e., multirotors). However, in several other UAS configurations such as fixed-wing vehicles or conventional helicopters may, if needed, rather account for servo dynamics acting on control surfaces or a swashplate. Again, the relevant servo angle dynamics can be captured by an identified first-order transfer function of the form $1/(1 + \tau_s s)$, with the servo time constant τ_s .

26.4 Airplane Modeling and Design

Ever since the beginning of aviation, a broad spectrum of airplanes has been built and operated successfully: size, speed, and maneuverability vary widely and as a function of application. Since design and modeling are strongly related, we want to first give an overview of the physical principles common to all such configurations, and provide analysis tools for characterizing static and dynamic properties of an airplane. The design problem somewhat constitutes the inverse problem: for specified target characteristics, the engineer needs to find a suitable configuration; we therefore provide a summary of design guidelines aimed at fast convergence to a suitable design. Finally, a simple and classical autopilot scheme is presented underlining the need for models also at that stage.

26.4.1 Forces and Moments

Consider Fig. 26.18 for the introduction of airplane geometry definitions and main forces. Forces and moments are reduced to the airplane center of gravity (COG). Note that the angle of attack (AOA) α is defined as the angle between the x -axis and the true airspeed vector \mathbf{v}_t projected into the body x - z -plane, β denotes the sideslip angle, causing a typically unwanted sideslip force Y , L and D denote lift and drag, W stands for the weight and T for thrust, which may act into a direction different from x (at a thrust angle ϵ_T). We furthermore write the aerodynamic moment vector as ${}^B\boldsymbol{\tau}_A = [L_A, M_A, N_A]^T$. Also note the introduction of the main control surfaces that are designed to mainly influence the aerodynamic moment: with ailerons, elevator,

and rudder, the roll (L_A), pitch (M_A), and yaw (N_A) moments are controlled. The indicated flaps, if available, are used for increasing lift for take-off and landing, in order to achieve a slower minimum speed.

Aerodynamic Forces and Moments

The aerodynamic forces and moments can be modeled to various accuracy using full 3-D CFD or with 2.5-D tools: Sect. 26.3.3 overviews such an approach which can be used to model the aerodynamic surfaces in incompressible flow. For enhanced accuracy, fuselages may be

Fig. 26.18 Geometric definitions and main forces acting on the airplane (general case, not in equilibrium)

considered using again a combination of potential flow (placing singularities) and boundary layer theory. Respective ready-to-use software such as AVL [26.17] and XFLR [26.12] is available for free.

The forces and moments may again be written with dimensionless coefficients as

$$L = \frac{1}{2} \rho V_t^2 c_L A, \quad (26.53)$$

$$D = \frac{1}{2} \rho V_t^2 c_D A, \quad (26.54)$$

$$M_A = \frac{1}{2} \rho V_t^2 c_M \bar{c} A, \quad (26.55)$$

with the wing area A , the mean chord length \bar{c} , and the true airspeed $V_t = \|v_t\|$. The moments L_A and N_A are made dimension-less with the wingspan b rather than the chord length.

Static Performance Considerations

Having characterized lift and drag of an airplane, three operating points are of particular interest.

First, stall is occurring at $c_{L,\max}$. This condition can be directly translated into constant-speed level-flight stall speed by applying the lift balance $L = mg$.

Second, the maximum c_L/c_D ratio, or the *glide ratio* characterizes the maximum aerodynamic efficiency, i. e., the operating point for maximum range (assuming constant propulsive efficiency).

Finally, the maximum c_L^3/c_D^2 ratio, or the *climb factor* describes the condition at which power consumption is minimized, thus maximizing flight time (again assuming constant propulsion unit efficiency).

The latter two conditions have direct interpretation in gliding (or propulsion shut-off), in terms of maximum distance reached per altitude lost and minimum sink rate, respectively. Again, corresponding velocities can be found using the lift balance.

Thrust

For detailed insight into the variety of propulsion systems and respective models, the interested reader is referred to [26.13, 18]. As an approximation for the important case of a propeller, the BEMT method as described in Sect. 26.3.4 is suggested. For many applications, choosing the propeller speed as the system input and neglecting motor dynamics is sufficient.

26.4.2 Static Stability

Various forms of stability constitute central characteristics of an airplane related to whether or not it can be flown by a human pilot or flight controller. Simple stability criteria can be derived by requiring reaction

forces and moments to be opposing a disturbance. We assume stationary conditions in the sense of constant linear and angular speeds: the respective force and moment balance is typically straightforward to apply in order to determine the starting point of the stability analysis.

Longitudinal Static Stability

We will take a close look at the example of longitudinal static stability playing a central role in airplane analysis and design. Leaving aside possible influence of the propulsion unit, the respective directional stability criterion is stated as

$$\frac{\partial c_M}{\partial \alpha} < 0, \quad (26.56)$$

at the equilibrium condition $c_M = 0$. Figure 26.19 illustrates an exemplary moment coefficient as a function of AOA. Note that elevator actuation will move this curve up and down, and with it the equilibrium point (2) toward higher or lower angles of attack (i. e., lower or higher trimmed speeds). Figure 26.20 illustrates the forces and moments in the stable equilibrium

Fig. 26.19 Moment coefficient c_M as a function of AOA α the equilibrium point (2) is stable for $\partial c_M / \partial \alpha < 0$ (brown curve)

Fig. 26.20 Forces and moments at the main wing and tail for zero lift (1), the stable equilibrium AOA (2), and for high lift (3). The forces and moments are drawn into the individual surfaces' aerodynamic centers. Note the tilted inflow at the tail due to downwash. The green filled circle denotes the overall airplane aerodynamic center (AC)

with a simplified airplane side-view as compared to the points (1) and (3), i. e., zero-lift ($\alpha = 0$) and high-lift, respectively. The stability criterion can be equivalently stated as: the airplane COG needs to be *in front* of the airplane aerodynamic center. Note the main parameters that influence the stability are tail lever arm, tail area, the *longitudinal dihedral* $\Delta\epsilon$ (Fig. 26.20 for its geometric definition), and the COG location along the x -axis.

26.4.3 Dynamic Model

While some core characteristics such as static stability and performance measures may already be established using aerodynamics coefficients only, we now turn to analyze the dynamics, since they provides a much richer insight into airplane characteristics.

For application of the 6-D (six-dimensional) rigid body dynamics (26.45), the forces and moments from the various sources need to be assembled and represented in the body frame

$${}^B\mathbf{F} = \begin{pmatrix} L \sin \alpha - D \cos \alpha + T \cos \epsilon_T \\ Y \\ -L \cos \alpha - D \sin \alpha + T \sin \epsilon_T \end{pmatrix} + {}^B\mathbf{W}, \quad (26.57)$$

$${}^B\boldsymbol{\tau} = \begin{pmatrix} L_A + L_T \\ M_A + M_T \\ N_A + N_T \end{pmatrix}, \quad (26.58)$$

with the weight in body coordinates ${}^B\mathbf{W} = {}^B\mathbf{R}_W[0, 0, -mg]^T$, and where the T-subscript indicates (possible) moment components from thrust. Note that the system inputs \mathbf{u} are hidden inside these forces and moments. Also be aware of α and β containing parts of the state vector

$$\alpha = \arctan2(u_t, u_i), \quad (26.59)$$

$$\beta = \arcsin(v_t/V_i), \quad (26.60)$$

where the true airspeed components are used

$${}^B\mathbf{v}_t := \begin{cases} u_t \\ v_t \\ w_t \end{cases} = {}^B\mathbf{v} - {}^B\mathbf{R}_W^W \mathbf{w}, \quad (26.61)$$

with the wind vector ${}^W\mathbf{w}$.

Furthermore, due to the airplane symmetry plane, the inertia matrix becomes

$${}^B\mathbf{I} = \begin{pmatrix} I_{xx} & 0 & I_{xz} \\ 0 & I_{yy} & 0 \\ I_{xz} & 0 & I_{zz} \end{pmatrix}. \quad (26.62)$$

Parametric Force and Moment Models

Let us consider the example of a simple airplane configuration with ailerons, a rudder and an elevator plus a propeller, driven by an electric motor at rotation speed ω_p .

We define the system input vector $\mathbf{u} = [\delta_a, \delta_e, \delta_r, \delta_T]$ as normalized aileron, rudder, and elevator action, $\delta_a, \delta_e, \delta_r \in [-1, 1]$ as well as (normalized) thrust $\delta_T \in [0, 1]$.

The fully parametric nonlinear model provided below largely follows [26.19]. We approximate the lift, drag as well as sideslip coefficients with polynomials in α and β

$$\begin{aligned} c_L &\approx c_{L,0} + c_{L,\alpha}\alpha + c_{L,\alpha^2}\alpha^2 + c_{L,\alpha^3}\alpha^3, \\ c_D &\approx c_{D,0} + c_{D,\alpha}\alpha + c_{D,\alpha^2}\alpha^2 + c_{D,\beta^2}\beta^2, \\ c_Y &\approx c_{Y,\beta}\beta. \end{aligned} \quad (26.63)$$

For many applications except slow flying airplanes, the second-order and third-order term of c_L can be omitted.

As far as the torques are concerned, we introduce also dependencies on normalized angular rates

$${}^B\boldsymbol{\omega}_n = (p_n, q_n, r_n)^T = \left(\frac{pb}{2V_t}, \frac{q\bar{c}}{2V_t}, \frac{rb}{2V_t} \right)^T. \quad (26.64)$$

A suitable approximation of the moment coefficients is now made as

$$\begin{aligned} c_L &\approx c_{L,0} + c_{L,\delta_a}\delta_a + c_{L,\beta}\beta + c_{L,p_n}p_n + c_{L,r_n}r_n, \\ c_M &\approx c_{M,0} + c_{M,\delta_e}\delta_e + c_{M,\alpha}\alpha + c_{M,q_n}q_n, \\ c_N &\approx c_{N,0} + c_{N,\delta_r}\delta_r + c_{N,\beta}\beta + c_{N,r_n}r_n. \end{aligned} \quad (26.65)$$

Finally, the propeller thrust force needs to be modeled. Using the advance ratio $J = \frac{2\pi V_t}{\omega_p d}$, with propeller diameter d , we can approximate the thrust coefficient

$$c_T \approx c_{T,0} + c_{T,J}J + c_{T,J^2}J^2. \quad (26.66)$$

The thrust is then obtained as

$$T = \rho \left(\frac{\omega_p}{2\pi} \right)^2 d^4 c_T. \quad (26.67)$$

Linearized Dynamics

As common throughout literature, the linearized airplane dynamics are written using Euler angles, which is why we will follow the same approach. But conceptually, they could be written in a singularity-free form using a minimal quaternion perturbation.

Typically, a separation into *longitudinal* and *lateral* dynamics is made, in order to assess related characteristics separately. Furthermore, the state is transformed to contain α , β , and V_t rather than $^B\mathbf{v}$.

The linear dynamics around a reference state \mathbf{x}_0 and input \mathbf{u}_0 vector takes the form

$$\Delta \dot{\mathbf{x}}_{\text{lon}} = \mathbf{A}_{\text{lon}} \Delta \mathbf{x}_{\text{lon}} + \mathbf{B}_{\text{lon}} \Delta \mathbf{u}_{\text{lon}}$$

and

$$\Delta \dot{\mathbf{x}}_{\text{lat}} = \mathbf{A}_{\text{lat}} \Delta \mathbf{x}_{\text{lat}} + \mathbf{B}_{\text{lat}} \Delta \mathbf{u}_{\text{lat}}.$$

The following formulation follows [26.19] to a large extent.

Figure 26.21 describes the separation in terms of inputs $\Delta \mathbf{u}$ and states $\Delta \mathbf{x}$ for the linearized system.

The longitudinal nonlinear equations are given as

$$\begin{aligned} \dot{q} &= \frac{1}{I_{yy}} [M_A + M_T - (I_{xx} - I_{zz})pr + I_{xz}(p^2 - r^2)], \\ \dot{V}_t &= \frac{1}{m} [-D \cos \beta + Y \sin \beta \\ &\quad + T \cos(\alpha - \epsilon_T) \cos \beta + mg_1], \\ \dot{\alpha} &= \frac{1}{\cos \beta} \left[\frac{1}{mV_t} (-L - T \sin(\alpha - \epsilon_T) + mg_3) + q_A \right], \\ \dot{\theta} &= q \cos \varphi - r \sin \varphi, \end{aligned} \quad (26.68)$$

Fig. 26.21a,b Linearized (a) longitudinal, and (b) lateral plants for inputs $\Delta \mathbf{u}$ (around \mathbf{u}_0) of the local states $\Delta \mathbf{x}$ (around \mathbf{x}_0)

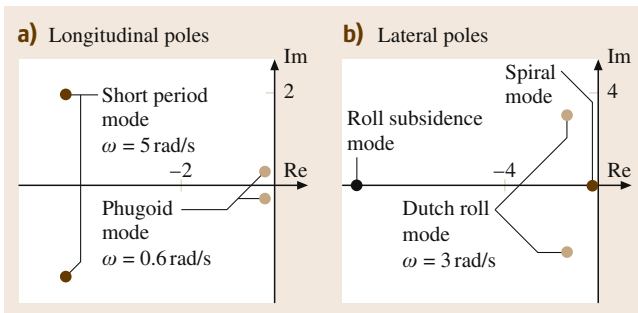

Fig. 26.22 (a) Longitudinal, and (b) lateral poles of an example aerobatic RC airplane

and the lateral nonlinear equations amount to

$$\begin{aligned} \dot{p} &= \frac{I_{zz}(L_A + L_T - T_p)}{I_{xx}I_{zz} - I_{xz}^2} - \frac{I_{xz}(N_A + N_T - T_r)}{I_{xx}I_{zz} - I_{xz}^2}, \\ \dot{r} &= \frac{I_{xz}(L_A + L_T - T_p)}{I_{xx}I_{zz} - I_{xz}^2} + \frac{I_{zz}(N_A + N_T - T_r)}{I_{xx}I_{zz} - I_{xz}^2}, \\ \dot{\beta} &= -r_A + \frac{1}{mV_t} [Y \cos \beta + D \sin \beta \\ &\quad - T \cos(\alpha - \epsilon_t) \sin \beta + mg_2], \\ \dot{\varphi} &= p + q \sin \varphi \tan \theta + r \cos \varphi \tan \theta, \end{aligned} \quad (26.69)$$

where the following terms were used

$$\begin{aligned} g_1 &= g(-\cos \alpha \cos \beta \sin \theta + \sin \beta \sin \varphi \cos \theta \\ &\quad + \sin \alpha \cos \beta \cos \varphi \cos \theta), \\ g_2 &= g(\cos \alpha \sin \beta \sin \theta + \cos \beta \sin \varphi \cos \theta \\ &\quad - \sin \alpha \sin \beta \cos \varphi \cos \theta), \\ g_3 &= g(\sin \alpha \sin \theta + \cos \alpha \cos \varphi \cos \theta), \\ q_A &= q \cos \beta - p \sin \beta \cos \alpha - r \sin \alpha \sin \beta, \\ r_A &= r \cos \alpha - p \sin \alpha, \\ T_p &= (I_{zz} - I_{yy})qr + I_{xz}pq, \\ T_r &= (I_{yy} - I_{xx})qp - I_{xz}qr. \end{aligned} \quad (26.70)$$

The linearizations of (26.68) and (26.69) are straightforward to obtain and not provided here due to space constraints. For a specific operating point, typically stationary ($\varphi_0 = 0$, $\theta_0 = \alpha_0$, and $^B\boldsymbol{\omega} = \mathbf{0}$), the standard tools of linear systems analysis can be employed. Most importantly, the *pole* locations in the imaginary plane will tell the characteristic modes and their dynamic stability. Figure 26.22 shows a pole location plot for an example RC airplane and introduces the related mode names.

In the case of a real pole π_i , it has the time constant $\tau_i = -1/\text{Re}(\pi_i)$. In the case of a complex conjugate pole pair, it is associated with a damping ratio $\zeta_i = -\text{Re}(\pi_i)/\sqrt{\text{Im}(\pi_i)^2 + \text{Re}(\pi_i)^2}$ and with an eigenfrequency $\omega_i = \sqrt{\text{Im}(\pi_i)^2 + \text{Re}(\pi_i)^2}$.

Figure 26.23 illustrates and characterizes the main modes.

26.4.4 Design Guidelines

Airplane design typically consists of the three stages *conceptual* design, *preliminary* design, and *detail* design. Here, we focus on the first two phases; due to space constraints, details of airplane structural design

and analysis are not covered here. The reader is referred to respective literature, e.g., [26.20], or [26.21], the latter covering RC-type aircraft. In the following, we provide a quick overview of practical guidelines for the typically iterative design process related to achieving characteristics as described above. The guidelines follow largely [26.22] and [26.18], with focus on slow-flying small-scale **UAS**.

Sizing and Geometry of Main Components

In the following, we provide some rules of thumb as initial guess for the design process in terms of sizing the wing, tail, control surfaces, and the propulsion unit. As a first and very general advice, the engineer is encouraged to minimize wetted area and cross section, as well as any kind of nacelles for increased aerodynamic efficiency.

Wing. First, an existing airfoil shall be chosen with characteristics meeting the requirements in the target flow regime (Re and Ma). When it comes to determining the overall wing size, a first estimate of design weight including structure, avionics, payload, propulsion unit, and energy storage is of crucial importance (26.2). With the target speed V_r and design lift coefficient c_l , a rough guess can be made for the wing area

$$A = 2mg/(\rho V_r^2 c_l) .$$

Concerning wing shape, clearly highest efficiency is reached with high aspect ratios (plus no multiple

lifting surfaces), and, at low Ma, no sweep-back – as long as still implementable with a structural concept and staying at reasonably high Re numbers. For high efficiency, it is advisable to achieve an elliptic lift distribution to some extent by geometry. For benign stalling characteristics, it is furthermore highly advisable to twist the wing leading edge downward with increased spanwise distance (which also influences the lift distribution).

Finally, some dihedral should be considered for roll stability.

Tail. Various types of tails and even *exotic* configurations like the canard have been suggested; here, we want to simply point out the importance of the so-called *tail volume coefficient*, c_{VT} and c_{HT} concerning vertical and horizontal tail, respectively,

$$c_{VT} = l_{VT} A_{VT} / (bA) , \quad (26.71)$$

$$c_{HT} = l_{HT} A_{HT} / (\bar{c}A) , \quad (26.72)$$

with the wing to vertical tail lever arm l_{VT} and the wing to horizontal tail l_{HT} (these are referenced to the individual mean 1/4-chord points). Typical values for small-size slow airplanes are $c_{VT}=0.02\text{--}0.04$ and $c_{HT} = 0.5\text{--}0.7$. Furthermore, care should be taken that control surfaces are not completely blanketed in the case of stall (for stall/spin recovery).

Control Surfaces. Ailerons typically extend from around 50% in span direction to 90%; in this setting, 20–30% of wing chord is suggested as aileron depth. Tail control surface depth is typically chosen around 40% of the respective chord.

Propulsion. Finally, some advice is given concerning the propulsion unit. Some **UAVs** are required to be handlaunched: note that this imposes limits on the overall maximum take-off mass and minimum/stall airspeed. Experience shows that reasonable limits are $<9\text{ m/s}$ minimum/stall speed and 7 kg airplane mass. For such small **UAVs**, a static thrust to weight ratio of at least 50% is highly recommended. In general, the propulsion unit must be sized to meet the specifications in terms of climb rates, maximum level flight speed and service ceiling. For the highest efficiency, the propulsion unit should be designed such as to provide highest efficiency at the design operating point (subscript r) $T_r/W = c_{D,r}/c_{L,r}$. For a hobbyist brushless DC outrunner type motor, the maximum power per motor mass ratio of 3.4 kW/kg can be used for estimation of the propulsion unit weight [26.23] (gearbox and propeller mass not included).

Fig.26.23a–d Characteristic trajectories of excited longitudinal modes (a,b) and lateral modes (c,d)

Handling Qualities

Manned aviation introduced the notion of *handling qualities*, assessing how well an aircraft can be flown by a human pilot as a basis for certification of both civil and military airplanes. Since UAS typically rely on autopilot systems enabling a certain degree of autonomy, these concepts may not be directly applied, but are still extremely relevant. Most importantly, the handling qualities concerning static and dynamic stability, as well as controllability determine the success of a UAS design.

While an autopilot can handle more and faster instabilities than a pilot, it can certainly not compensate for missing actuation authority. As detailed in Sect. 26.7, it is advisable to implement de facto manual operation mode as a testing, backup, or even standard operation mode, in which the airplane is either steered manually or through some stability augmentation system (SAS). Therefore, it is highly advisable that the resulting system complies with the following core requirements (simplified from [26.18]):

- Static longitudinal stability: most aft COG at least 5% of \bar{c} in front of aerodynamic center (static margin, SM).
- Phugoid damping $\zeta_{ph} > 0.2$.
- Short-period oscillation $\omega_{sh} > 2$, $\zeta_s > 0.5$.
- Spiral mode may be unstable, if $\tau_{sp} > 20$ s.
- Roll acceleration at maximum aileron deflection $|\dot{p}(\delta_{a,max})| > 5 \text{ rad/s}^2$, roll subsidence time constant $\tau_{rs} < 1$ s.
- Dutch roll damping $\zeta_{dr} > 0.1$.
- Spins shall not be entered abruptly and must always be recoverable.

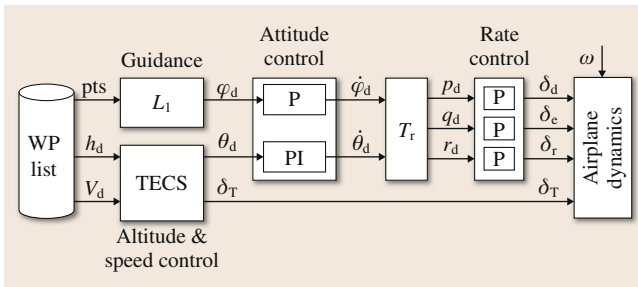

Fig. 26.24 Simple cascaded airplane guidance and control system

Fig. 26.25 Illustration of L_1 lateral guidance

26.4.5 A Simple Autopilot

As shown earlier, airplane dynamics are nonlinear multiple-input-multiple-output (MIMO) systems with a significant amount of cross-coupling, thus they are inherently challenging to control. While a plethora of control strategies have been suggested as autopilots, we will provide a simple yet functional approach here that employs the popular concept of *cascaded* control loops as well as simple linear single-input-single-output (SISO) PID controllers acting on subparts of the dynamics. This approach is still widely deployed and well-understood, despite the fact that more advanced controllers, such as model-based linear quadratic regulators (LQR) with gain scheduling or nonlinear dynamic inversion (NDI) may achieve significantly better performance. Reference [26.24] constitutes an excellent reference for in-depth treatment of small UAS guidance and control with cascaded control loops.

Cascaded Control Architecture

Figure 26.24 introduces the overall controller architecture. It presents the (typical) separation of per-axis *rate controllers* at the innermost loop, followed by an *attitude* controller and a combined altitude and speed controller TECS (total energy control system), as well as by a lateral L_1 guidance. In general, care must be taken to separate successively closed loops by around a decade in terms of bandwidth.

Assuming little cross-axis sensitivity, the rate controllers may be implemented with simple individual P-controllers, optionally with $1/V_t^2$ gain scaling. Also the attitude controllers can be as simple as P and PI-controllers for roll and pitch, respectively. Note that the desired roll and pitch angle derivatives need to be transformed in the static block T_r into angular reference rates: this can be achieved by applying the inverse Jacobian J_r from (26.42) – where the missing yaw angle time derivative can be computed from the coordinated turn constraint $\beta = 0$, $\dot{\beta} = 0$ in (26.69)

$$\dot{\psi} = -\frac{g \sin \phi}{V_t \cos \alpha \cos \phi} + \frac{\dot{\theta}_d \sin \phi}{\cos \phi \cos \theta} \quad (26.73)$$

The combined altitude and speed controller (TECS) inspired from [26.25] uses the difference to the reference altitude $\Delta h = h_d - h$ to compute a desired climb rate of the form $\dot{h}_d = \dot{h}_{traj} + K_{P,alt} \Delta h$, with the given trajectory rate of climb \dot{h}_{traj} and a P-gain $K_{P,alt}$. Knowing the speed and corresponding angle of attack, \dot{h}_d can be simply converted into a desired pitch angle θ_d – to be saturated according to maximum thrust (climb) and drag (sink). Since climb rate must be provided via

additional thrust, the respective power component is computed as $\Delta T_{\text{climb}} = mgh_d/V_t$. Concerning the speed control, the second thrust component is computed with the P -gain $K_{P,\text{vel}}$ as $\Delta T_{\text{acc}} = mK_{P,\text{vel}}\Delta V_t$.

As a last autopilot component, the \mathcal{L}_1 lateral guidance [26.26] proceeds as follows (illustrated in Fig. 26.25): a reference circular path of radius R is calculated that intersects the reference path given by the waypoint sequence at look-ahead distance L_1 . In or-

der to track this reference, a centripetal acceleration of V_t^2/R is needed, which can now be directly translated into a desired roll angle $\varphi = \arctan(V_t^2/(Rg))$ corresponding to a coordinated (level) turn – saturated with maximum bank angles.

Note that the suggested scheme should be enhanced by stall prevention and recovery (AOA monitoring and control), as well as by preventing sideslip for safer (and more efficient) operation.

26.5 Rotorcraft Modeling and Design

Various types of rotorcraft UAV configurations have been developed in the past (some examples are shown in Fig. 26.26), from helicopter-type UAVs such as [26.27, 28], over a vast selection of multicopter configurations such as [26.29, 30] and tail-sitter vehicles such as [26.31, 32] up to completely new types of flight mechanisms [26.33, 34]. The design, modeling, and system analysis process for all these RW-UAS types is essentially very similar and is largely based on the methodologies originally developed within the aerospace community for full-scale rotorcraft design and evaluation [26.15, 35]. In this context, it is important to realize that the rotorcraft design process goes beyond mere efficiency and payload considerations focused on the propulsion components (e.g., using BEMT). Designing an effective RW-UAS should in principle also include flight dynamics assessments of the entire robotic flight platform.

Flight performance assessment is commonly based on one of two types of modeling approaches referred to as *quasi-steady* and *hybrid* [26.36]. The quasi-steady modeling method employs a single rigid body representation of the aircraft affected by the steady-state forces and moments originating from the propulsion subsystem. Hybrid models treat the rotorcraft as a multibody system where the dynamics of the aircraft body are coupled with additional dynamics of the rotor or propeller blades (e.g., blade flapping dynamics). For propeller-based RW-UAS like multicopter and tail-sitter vehicles using the quasi-steady approach to, e.g., model attitude dynamics is most widespread. This may be related to the fact that for these vehicle configurations, properly accounting for motor dynamics may be more relevant than accounting for high-order effects related to structural deformations of the propeller blades. For helicopter-type UAVs the hybrid approach is more common as some dynamic modes of the rotor system are likely to couple with the attitude dynamics of the main rotorcraft body. Note that a proper application of the hybrid approach is considerably more involved than using

quasi-steady models and should only be resorted to if justified.

A detailed treatment of the specific modeling and design procedures for every robotic rotorcraft configuration is beyond the scope of this chapter and thus the presented considerations focus on helicopter-type and multicopter UAVs. Based on the extensive theoretical aerospace-related background available in [26.14, 15, 35] amongst others, models for the most relevant rotor respectively propeller forces and moments are presented and subsequently appended to the rotorcraft body dynamics discussed in Sect. 26.3.6. A simplified

Fig. 26.26 (a) Conventional helicopter configuration. Swiss UAV Neo S-300. (b) Quadcopter configuration. Microdrones MD4-1000

hybrid modeling approach is introduced and reductions to quasi-steady models are discussed where applicable. Finally, a few metrics meaningful for rotorcraft design and control purposes are discussed and summarized shortly.

26.5.1 Mechanical Design of Rotors and Propellers

The main control mechanism for any RW-UAS is its rotors or propellers. Accordingly, to understand the working principles and the dynamics of the rotorcraft type of aircraft, it is worth investigating a few of the main design characteristics found in these flying mechanisms.

The following discussion focuses on the operation principles of helicopter rotors and will be expanded to propellers subsequently. Figure 26.27 visualizes the typical rotor degrees of freedom realized via the *flap*, *lead-lag* and *feathering* (also referred to as *pitch*) hinges. The flap hinge allows the rotor blade to flap due to aerodynamic and inertial loads affecting the blade body during flight. The lead-lag hinge responds to lateral rotor blade moments due to Coriolis forces related to flapping. Where the flap and the lead-lag hinges are usually passive, possibly augmented with spring or damper elements, the pitch hinge is active in order to adjust the blade angle of attack and thus the generated aerodynamic forces.

Three types of rotor hubs are typically found in modern helicopters referred to as *teetering*, *articulated*, and *hingeless* depending on the mechanical realization of the flap hinge (Fig. 26.28). In the case of teetering rotor, a single hub flap hinge is located directly on the rotorshaft axis, rigidly connecting a set of two rotor blades. For the articulated rotor, the blades and the rotor hub are connected via mechanical hinges at a specific offset e from the rotor shaft axis, thus allowing each blade to flap individually. The hingeless rotor flaps through the deformation of elastic elements

Fig. 26.27 Typical hinge configuration of an articulated rotor blade

connecting the hub with each individual rotor blade or directly through structural deformation of the blades themselves. In this case, a virtual hinge offset can be defined at the intersection of the rotor hub plane and the tangent to the deflecting blade body at 75% of the rotor radius [26.14]. The specific characteristics of the flap hinge (offset from rotor shaft, stiffness, and damping) are fundamental for rotor blade flapping and in consequence for the rotorcraft pitch and roll dynamics as discussed later.

In the case of most propeller-based rotary-wing (RW) UAVs (e.g., multicopter systems) the feathering and lead-lag degrees of freedom do not exist. Nevertheless, propeller-based RW-UAVs may exert blade flapping by deformation of the propeller blades.

26.5.2 Rotorcraft Dynamics

As discussed in Sect. 26.3.6, the main rotorcraft body dynamics can be directly described by the simplified differential (26.45) which for most rotorcraft systems maintain the presented mathematical structure. For helicopter-type and multicopter UAV configurations the dominant set of external forces and moments affecting these dynamics can be summarized as

$$\mathbf{F} = \mathbf{F}_G + \sum_{i=1}^{N_r} \mathbf{F}_T^i + \sum_{i=1}^{N_r} \mathbf{F}_H^i + \mathbf{F}_D, \quad (26.74)$$

$$\boldsymbol{\tau} = \sum_{i=1}^{N_r} \boldsymbol{\tau}_Q^i + \sum_{i=1}^{N_r} \boldsymbol{\tau}_T^i + \sum_{i=1}^{N_r} \boldsymbol{\tau}_H^i + \sum_{i=1}^{N_r} \boldsymbol{\tau}_\beta^i. \quad (26.75)$$

The vector \mathbf{F}_G represents the weight force and \mathbf{F}_T^i is the thrust force of the i -th rotor or propeller out of the total set of N_r rotors or propellers (Fig. 26.29). These forces are related to the body heave dynamics but due

Fig. 26.28 Rotor hub design concepts of a teetering rotor, an articulated rotor with hinge offset e and a hingeless rotor with a virtual hinge offset e

to the underactuation of most rotorcraft are also responsible for the lateral rotorcraft acceleration.

The additional in-plane hub forces F_H^i represent drag-related effects that may be neglected near hover but become more dominant for higher lateral flight velocities [26.15]. The vector F_D represents the drag force associated with the rotorcraft main body. For simplicity's sake, it is assumed that the center of pressure of the rotorcraft body is collocated with its center of gravity which is not necessarily the case.

The relevant set of external moments is defined by the torques τ_Q^i affecting the vehicle yaw dynamics, the thrust-induced moments τ_T^i , the moments introduced by the hub forces τ_H^i and the flapping moments related to the rotor hub stiffness τ_β^i .

More explicit expressions for the respective force and moment terms may be found in Tables 26.6 and 26.7, where T_i is the averaged thrust force magnitude, H_x^i and H_y^i are the hub force components along the rotorcraft body frame x - and y -axes, and Q_i is the torque generated by the i -th propeller or rotor. The aerodynamic drag of the main rotorcraft body, represented by the components D_x , D_y , and D_z , has been discussed in some detail in Sect. 26.3.5.

The vector ${}^B r_i$ corresponds to the displacement of the i -th rotor or propeller hub from the rotorcraft body frame origin and ${}^B n_i$ is the tip-path plane normal of the i -th propeller or rotor disk as explained in [26.37].

The coefficients β_{1c} and β_{1s} represent the longitudinal and lateral flapping coefficients [26.15] describing the tilting of the rotor or propeller disk as elaborated in more detail later in this section. Finally, the parameter k_b^i corresponds to the flapping spring stiffness of the i -th rotor or propeller hub. In the case of articulated or teetering hubs this torsional spring stiffness represents potential flap hinge springs and in case of hingeless hubs approximates

Table 26.6 Typical rotorcraft forces

Type of force	Expression

Thrust	${}^B F_T^i = {}^B n_i T_i$
Hub forces	${}^B F_H^i = \begin{pmatrix} H_x^i \\ H_y^i \\ 0 \end{pmatrix}$
Rotorcraft body drag	${}^B F_D = \begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix}$

Fig. 26.29 A conventional helicopter and a quadcopter platform. Flapping angles have been exaggerated and only the rotor and propeller forces relevant near hover have been visualized

the structural bending stiffness of a particular rotor or propeller.

In the case of a helicopter tail rotor, flapping is usually neglected and the thrust direction is modeled as, e.g.,

$${}^B n_i = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}. \quad (26.76)$$

To finalize the models of these external forces and moments, the respective aerodynamic effects as well as the role and characteristics of blade flapping must be discussed next.

26.5.3 Simplified Aerodynamics

In order to accurately predict the forces and moments generated by a rotorcraft system, accounting for various ranges of operation conditions, detailed design specifications, aerodynamic interactions between the different rotors or propellers and possibly the rotorcraft body itself, highly sophisticated aerodynamics simula-

Table 26.7 Typical rotorcraft moments

Type of moment	Expression
Torque	${}^B \tau_Q^i = \begin{pmatrix} 0 \\ 0 \\ Q_i \end{pmatrix}$
Thrust moment	${}^B \tau_T = {}^B r^i \times {}^B f_T^i$
Hub moment	${}^B \tau_H^i = {}^B r^i \times {}^B f_H^i$
Flap moment	${}^B \tau_\beta^i = k_b^i \begin{pmatrix} -\beta_{1s}^i \\ \beta_{1c}^i \\ 0 \end{pmatrix}$

tion tools are required. Such tools are usually not easily accessible to or operated by the roboticist and may hide some of the fundamental flight dynamics characteristics of a particular platform due to the involved complexity. For a repeated evaluation of the general flight properties of a rotorcraft it may thus be preferable to derive approximate, analytical models of the aerodynamic forces and moments. This may provide profound insight into the core working principles of rotorcraft operation.

The general approach to derive such models is the employment of **BET** as partially presented in Sect. 26.3.4. **BET**, as opposed to **BEMT** or **MT**, maintains the notion of individual rotor or propeller blades. Hence, it may account for changes in the angle of attack α , the aerodynamic inflow velocities U_T and U_P and in consequence of the local lift and drag increments dL and dD , not only in function of the radial position r of the observed airfoil segment but also in dependency of the blade azimuth ξ . To further the understanding of this dependency in ξ , one may examine Fig. 26.16 as well as Fig. 26.30 where the hub coordinate frame H is introduced.

The perpendicular and tangential inflow velocities U_P and U_T (and thus also α) are strongly related to the rotor angular speed Ω and the induced inflow velocity v_i (as discussed for **BEMT**). In flight operation beyond hover, these inflow velocities are also affected by the rotorcraft linear and angular velocities ${}^B\mathbf{v}$ and ${}^B\boldsymbol{\omega}$, as well as the potential flapping motion of the rotor or propeller blades. From the perspective of a revolving rotor or propeller blade, these additional inflow velocities vary periodically in function of ξ .

Inspecting Fig. 26.30, one can establish the following relations for the airfoil inflow velocities [26.35]

$$U_T = \Omega(e + r) - v_y + \beta\omega_x r, \quad (26.77)$$

$$U_P = v_i - w + \omega_y(e + r) + \dot{\beta}r - \beta v_x. \quad (26.78)$$

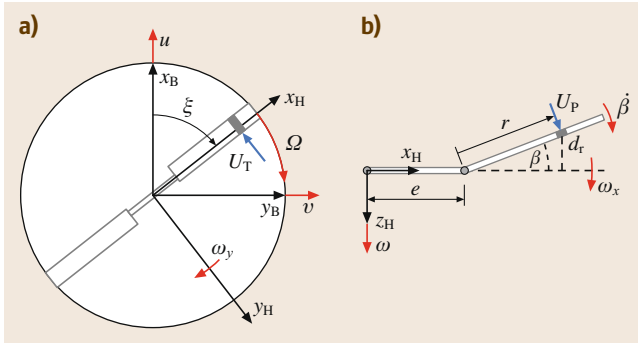

Fig. 26.30 (a) Top view of revolving rotor/propeller blade and the relevant velocities. (b) Side view of revolving rotor/propeller blade and the relevant velocities

The linear and angular velocities v_x , v_y , ω_x , and ω_y correspond to the projections of the vehicle body velocities u , v , p , and q into the hub frame H

$$v_x = u \cos \xi + v \sin \xi, \quad (26.79)$$

$$v_y = v \cos \xi - u \sin \xi, \quad (26.80)$$

$$\omega_x = p \cos \xi + q \sin \xi, \quad (26.81)$$

$$\omega_y = q \cos \xi - p \sin \xi. \quad (26.82)$$

For helicopter-type UAVs the azimuth dependency of α may also be related to periodic changes in the blade pitch angle θ . For helicopter configurations the feathering angle θ can usually be controlled collectively for the entire rotor disk or cyclically in dependency of the blade position ξ using a swashplate mechanism [26.38]

$$\theta = \theta_0 + \theta_{1c} \cos \xi + \theta_{1s} \sin \xi. \quad (26.83)$$

The swashplate mechanism essentially provides the means to adjust the collective pitch angle θ_0 as well as the cyclic pitch angles θ_{1c} and θ_{1s} individually. Note that for twisted propeller or rotor blades θ_0 merely represents the pitch angle at the blade root and an additional term accounting for the radial variation in pitch must be introduced [26.14].

By altering θ_0 , the swashplate provides some control over the average angle of attack of the entire rotor disk and thus the generated average thrust and torque. Similarly, varying the cyclic components creates a lift imbalance between opposing sides of the rotor disc. This lift imbalance induces a periodic flapping motion of the individual rotor blades (also depending on ξ) which affects the pitch and roll moments τ_β and τ_T . For helicopter-type UAVs this is the main control mechanism for the pitch and roll attitude dynamics.

For the majority of multicopter vehicles θ_0 is usually fixed and the cyclic angles do not exist ($\theta_{1c} = \theta_{1s} = 0$). In this case, attitude control is realized through τ_T only by changing the propeller speed Ω_i of the individual propellers.

To describe the aforementioned periodic changes in blade flapping the following representation of the flapping angle β is customary when modeling rotorcraft dynamics [26.39]

$$\beta = \beta_0(t) + \beta_{1c}(t) \cos \xi(t) + \beta_{1s}(t) \sin \xi(t). \quad (26.84)$$

The coefficient $\beta_0(t)$ corresponds to the coning angle of the entire rotor or propeller disc, whereas $\beta_{1c}(t)$ and $\beta_{1s}(t)$ are the longitudinal and lateral disk tilting angles.

Unlike the blade pitch coefficients in (26.83), the flap coefficients in (26.84) are assumed to be functions of time t which is later exploited when modeling flapping dynamics.

Although it is crucial to capture all these periodic dependencies in ξ , it can be obstructive for the purpose of creating an efficient rotorcraft simulation. Directly simulating the body dynamics (26.45) under the influence of the external forces and moments (26.74) and (26.75) while accounting for all dependencies in ξ , would require the blade motion to be simulated step by step while moving around the rotor or propeller shaft. This can lead to comparatively stiff differential equations which may be hard to simulate efficiently.

An alternative approach is to derive simplified force and torque models by integrating the lift and drag increments along the rotor or propeller radius, summing over the number of blades N_b and averaging around the rotor azimuth as

$$T = \frac{N_b}{2\pi} \int_0^{2\pi} \int_0^R dL, \quad (26.85)$$

$$Q = \frac{N_b}{2\pi} \int_0^{2\pi} \int_0^R r \left(dD + \frac{U_P}{U_T} dL \right), \quad (26.86)$$

$$H_x = \frac{N_b}{2\pi} \int_0^{2\pi} \int_0^R \sin \xi \left(dD + \frac{U_P}{U_T} dL \right), \quad (26.87)$$

$$H_y = \frac{N_b}{2\pi} \int_0^{2\pi} \int_0^R \cos \xi \left(dD + \frac{U_P}{U_T} dL \right). \quad (26.88)$$

Combining (26.77) to (26.88) with (26.12), (26.13), (26.27), and (26.33) and assuming simple rotor or propeller blade geometries (e.g., linear blade twist) the above expressions can be evaluated algebraically, e.g., using a symbolic computation program. As opposed to BEMT these averaged aerodynamic formulations are capable of accounting for the effects of the periodic changes of inflow velocities such as, e.g., the *dissymmetry of lift* phenomenon [26.15] as well as for the varying blade feathering and flapping angles.

To gain some appreciation of how these averaged models may be useful in providing insight into the core characteristics of rotorcraft operation, a strongly simplified thrust model directly resulting from (26.85) under the assumption of hover and negligible flapping angles is given as an example

$$T = \left(k_{T1} \theta_0 + k_{T2} \frac{v_0}{\Omega} + k_{T3} \right) \Omega^2. \quad (26.89)$$

The coefficients k_{T1} , k_{T2} , and k_{T3} essentially depend on aerodynamic and geometric rotor or propeller properties. As one may deduce directly from (26.89), thrust is a linear function of the collective pitch angle θ_0 and the average induced rotor or propeller inflow velocity v_0 which is further defined in the next section.

26.5.4 Nonuniform Inflow

In order to account for the varying induced flow field over the rotor or propeller disk in hover and forward flight, the following approximate induced inflow distribution may be assumed as discussed in [26.14]

$$v_i = v_0 + \frac{r}{R} (v_{1c} \cos \xi + v_{1s} \sin \xi). \quad (26.90)$$

The velocity component v_0 represents the average induced inflow at the center of the modeled rotor respectively propeller disc. It is directly related to the thrust level the rotor or propeller is operating at and may be computed, e.g., based on the iterative method discussed in [26.15]. The inflow coefficients v_{1c} and v_{1s} account for changes in the induced flow field due to lateral rotorcraft flight velocities. Various steady-state models for v_{1c} and v_{1s} have been proposed in the past with moderate prediction quality only.

Reference [26.40] presents these models in detail and discusses an alternative method which also accounts for transient effects. Accounting for inflow dynamics, the transient response of v_0 , v_{1c} , and v_{1s} to, e.g., sudden blade pitch changes can be captured and the aforementioned iterative computations may be avoided.

26.5.5 Flapping Dynamics

The dynamics of rotor or propeller flapping corresponds to a second-order differential equation of the flapping angle β which essentially represents an aerodynamically damped oscillator [26.35]

$$\ddot{\beta} = \ddot{\beta}(\xi, \Omega, u, v, w, p, q, \dot{p}, \dot{q}, \beta, \dot{\beta}, \theta). \quad (26.91)$$

Reference [26.41] and references therein elaborate the modeling process required to derive the above differential equation from first principles.

As for the simplified aerodynamic forces and moments, the dependency of (26.91) on rotor azimuth is important but problematic for efficient blade flap simulations. Here, the averaging operation discussed in [26.39] has been employed. This essentially leads to the following differential equation of the flapping coef-

ficients β_0 , β_{1c} and β_{1s}

$$\begin{aligned}
 A_{\ddot{\beta}}\ddot{\beta} + A_{\dot{\beta}}\dot{\beta} + A_{\beta}\beta &= A_{\theta}\theta + A_{\omega}\omega + A_v v, \\
 \beta &= \begin{pmatrix} \beta_0 \\ \beta_{1c} \\ \beta_{1s} \end{pmatrix}, \quad v = \begin{pmatrix} v_0 - w \\ v_{1c} \\ v_{1s} \end{pmatrix}, \\
 \omega &= \begin{pmatrix} p \\ q \\ \dot{p} \\ \dot{q} \end{pmatrix}, \quad \theta = \begin{pmatrix} \theta_0 \\ \theta_{1c} \\ \theta_{1s} \end{pmatrix}.
 \end{aligned}
 \tag{26.92}$$

The involved matrices from $A_{\ddot{\beta}}$ to A_v depend on an abundance of aerodynamic, geometric, inertial, and structural parameters of the modeled rotor or propeller system as well as on the lateral flight velocity of the rotorcraft. The structure of these matrices is thus strongly related to the type of rotor or propeller hub that is being modeled. From the resulting mathematical relations it is for example possible to conclude that for a teetering rotor without hinge springs, the maximal flapping response β to a cyclic pitch input in θ will follow with a 90° phase shift in rotor azimuth [26.15].

Considering the body time constants of most rotorcraft configurations in comparison with the time constants of the above dynamics, one may in general assume that the fast poles in (26.92) are negligible and they mostly represent rotor or propeller vibrations. Accordingly, (26.92) is often reduced to a first-order differential equation by introducing the assumption $\ddot{\beta} = 0$. For very rigid rotors or propellers one may even assume $\dot{\beta} = 0$ and compute the steady-state flapping response only (quasi-steady model). However, this is not the case for all RW-UAS configurations. To what degree higher order effects such as flapping or inflow dynamics have to be accounted for, depends on the level of frequency separation between the body poles versus the poles of the rotor dynamics.

26.5.6 Flight Dynamics Assessment

Assembling the dynamics of the rotorcraft body with the forces and moments defined in the previous section, as well as possibly introducing higher order effects such as blade flapping and inflow dynamics, results in a set of nonlinear differential equations representing the flight characteristics of the modeled platform. In order to inspect these flight characteristics one may

implement a flight simulator based on this set of nonlinear differential equations and analyze the simulated flight responses. The linearization process presented in Sect. 26.3.6 may provide additional conclusions and is often followed by a separation into subsystems analyzed individually.

One of the most crucial rotorcraft subsystems corresponds to the pitch and roll attitude dynamics as it is this subsystem which ultimately defines how agile, stable, or accurate a rotorcraft may be able to fly in the horizontal plane of motion. Assuming near hover operation and neglecting higher order dynamics, the linearized open-loop roll dynamics for example, can usually be reduced to a first-order transfer function

$$G(s) = \frac{P(s)}{U(s)} = \frac{K_p}{s - D_p}. \tag{26.93}$$

The frequency function $P(s)$ represents the Laplace transform of the rotorcraft roll rate p and $U(s)$ the Laplace transform of a control input affecting the roll subsystem. For a helicopter, this control input commonly corresponds to a cyclic swashplate command and for a quadro-copter to the differential speed between two propellers on opposing sides of its airframe. The abstracted system parameter K_p corresponds to the so-called *roll control derivative* and D_p to the so-called *roll damping* [26.37]. The control sensitivity K_p defines how strong the initial rotorcraft roll acceleration \dot{p} will respond to a control input represented by $U(s)$. The parameter D_p defines how well the system's dynamic response will be damped in the following. For hybrid rotorcraft models the corresponding transfer functions are generally of higher order but are equally useful when analyzed with the well-known tools of linear system theory [26.15, 35].

In general, these transfer functions and the resulting metrics such as, e.g., K_p and D_p can be derived in dependency of a specific subset of physical rotorcraft parameters. Using these simple metrics and including the knowledge that may be gathered from the nonlinear flight simulator, flight performance trends can be assessed depending on the parameters of the UAV configuration under investigation. Such parameters may for example include the body pitch and roll inertia, the location of the body center of gravity or the location of the rotors or propellers. The fundamental understanding gained in this evaluation process is crucial for the development of effective robotic flight systems and the required control laws.

26.6 Flapping Wing Modeling and Design

A variety of animals, from insects to birds, are capable of flight maneuvers which are presently impossible in micro aerial vehicles, such as flying in turbulence or cluttered airspace. Additionally, animals are more maneuverable and can fly longer distances. People have made many attempts at building flapping robots or ornithopters. While several are successful, many either never take off or fly only for a short duration due to their higher complexity or poor design. Until recently, ornithopters represented a niche of flying vehicles. The development of lithium polymer batteries produced a light-weight high-power energy resource to power ornithopters. Among the first successful electric ornithopters were the Caltech and Aerovironment microbots in 1998 [26.42, 43]. Many designs still fail to fly despite the rapidly increasing population building electric ornithopters. A major problem in most designs is an inability to generate enough lift to take off in the first place. This precludes additional flight research, such as maneuverability, flight distance or time. Engineers have believed that flapping wings are essential to further development of micro aerial vehicles since the first electric ornithopters took off and biologists started to understand the aerodynamics of flapping insect wings. The main reason behind this focus is the idea that they are aerodynamically more efficient at the small Reynolds number of insects (10–10 000) when viscosity effects start to dominate airflow.

26.6.1 Aerodynamic Mechanisms

Our understanding of insect aerodynamics provides us with the most detailed model of the aerodynamic function of a flapping wing [26.45]. There is some evidence that wing flexibility can improve aerodynamic performance of a flapping wing by roughly 10% [26.46] if the angle of attack is not optimized for a stiff wing. However, a parametric study using a robot model of an insect wing suggests that wing flexibility does not improve performance if we can optimize angle of attack independently of wing stiffness [26.47]. Ignoring aeroelastic effects that change angle of attack distribution, the key known aerodynamic mechanisms of a flapping wing are [26.45]:

1. A stable leading edge vortex (LEV) that enables the wing to operate at high angles of attack without stall during the quasi-steady mid-stroke phase (Fig. 26.31). During stroke reversal the aerodynamics is not quasi steady. In this phase, five additional effects are thought to be important:

2. *Added mass* effects due to fluid acceleration in response to the reversal.
3. The Wagner effect explaining that changes in vortex strength need time to build-up over a few chord lengths of travel.
4. Rotational lift due to the timing of changes in angle of attack during stroke reversal and its effect on vortex lift through the *Kramer effect*.
5. Wake capture when the wing reverses direction and interacts with the momentum jet of its shed wake.
6. Clap and fling when the wings become close enough to (nearly) touch and air is forced out of the cavity formed by the two wings and sucked back in, which can increase lift [26.48].

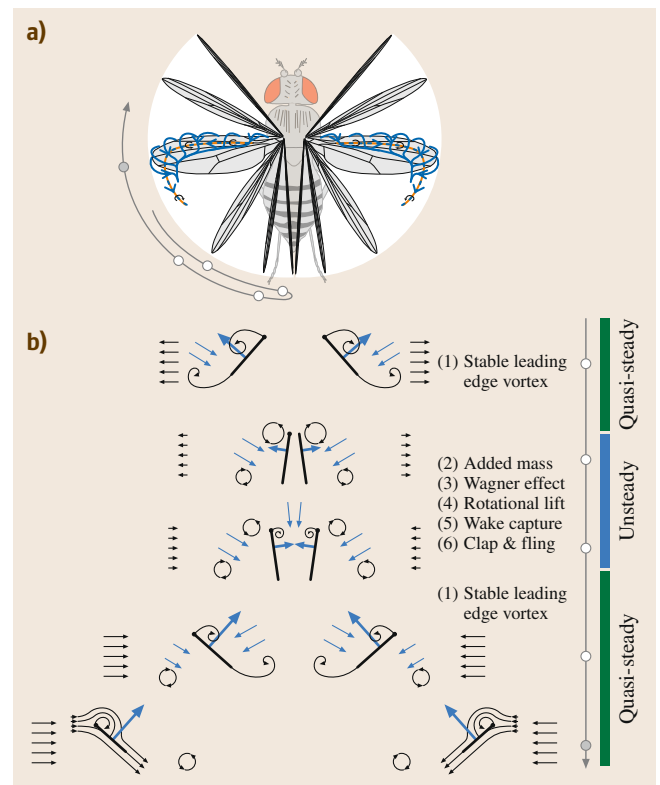

Fig. 26.31a,b Flapping insect wing aerodynamics can be understood through the interaction of a myriad of complex aerodynamic mechanisms. **(a)** The key high-lift mechanism insects employ, is a stable leading edge vortex (LEV) generated during the up and downstroke. **(b)** A flapping cycle consists of a quasi-steady part during which the wing accelerates little. During this phase, the stable LEV is the key high-lift mechanism (1). During stroke reversal there is evidence that up to five effects (2)–(6) could be important (after [26.44])

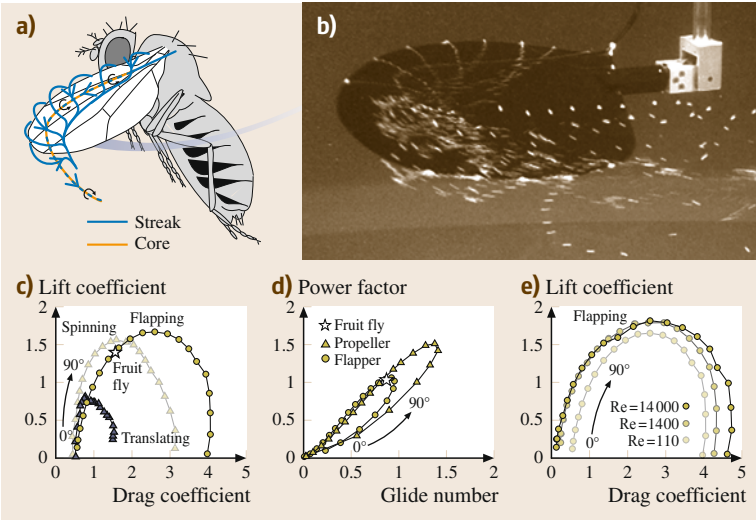

Fig.26.32a–e The aerodynamics of a flapping (insect) wing scale from insect to bird scale. **(a)** A stable LEV enables flapping wings to operate at high angles of attack without stall. **(b)** The key parameter explaining LEV stability is the wing’s swing, its spinning motion, as demonstrated by this spinning model of a fly wing which generates a stable LEV and similarly elevated forces as in flapping wings. **(c)** At insect scale fixed (translating) wings underperform, whereas flapping and spinning wings generate similarly high lift. Spinning wings generate less drag which makes them more efficient. **(d)** The power factor of a spinning wing is higher than for a flapping wing, higher indicating that less power is needed to support body weight. **(e)** The dimensionless lift and drag averaged over a full flapping cycle is independent of scale to within good approximation (Reynolds number 110: fruit fly: 1400; house fly: 14 000; hummingbird). This makes flapping wing aerodynamics scalable enabling the use of dimensional analysis [26.49]

There exist, however no quantitative experimental studies or theories that fully dissect these effects and quantify their relative importance for aerodynamic lift and power. While flapping wing aerodynamics is complex and not fully understood, it is simple from a robot design perspective, because it is scalable from insect to bird size (Fig. 26.32). This enables prototyping at larger, more cost effective, scales and enables scaling the design down as technology advances, and smaller components and fabrication methods become

available [26.49]. Flapping wings generate more lift than translating wings because they generate a stable LEV. To generate a stable vortex over the whole wing, the aspect ratio with respect to the center of rotation needs to be equal to or smaller than about 4 [26.53]. Flapping wings with an aspect ratio larger than 4 can stall outboard [26.53]; whereas more stubby flapping wings cannot. This can explain why the majority of insect, bird, and bat wings have an aspect ratio of around 2–4 with respect to the *shoulder* joint [26.53]. The

Fig.26.33a–c Examples of three different types of successful flappers. **(a)** Jaap Oldenkamp, Delfly II (after [26.49, 50]), **(b)** Nano Hummingbird (after [26.51]), **(c)** RoboBee (after [26.52])

main advantage of stubby wings is that they do not stall at high angles of attack enabling animals to take-off and land vertically by increasing angle of attack instead of flapping frequency [26.53] using LEVs [26.54]. Insects [26.55], bats, hummingbirds [26.56], and other birds [26.57], but also auto rotating seeds generate stable LEVs. This shows that stable LEVs are a convergent evolutionary solution for high lift at high angle of attack in nature [26.53].

Comparison of flapping versus spinning (propeller-like) insect wings shows spinning insect wings generate similar elevated lift forces by generating a LEV at lower drag. Helicopters with stubby rotors are, therefore, aerodynamically more efficient than stubby flapping wings, because they need less power to fly, as qualitatively presented in Fig. 26.32d [26.49]. This is confirmed experimentally for the most advanced hovering ornithopter at present, the Nano Hummingbird [26.51]. Comparing its flapping wing with a spinning wing showed for various forward speeds that flapping wings require more power for the same lift, in part due to aerodynamics [26.49, 53], and in part due to inertia losses [26.49, 51]. The key advantage of flapping wings seems to be the potential for extreme maneuverability and robustness. For instance, flapping wings may fare better in turbulence, close to the ground, near vertical surfaces and through clutter, when helicopters can become unstable due to stall and complex rotor-wake interactions [26.58].

26.6.2 Sizing New Flappers

An improved understanding of the detailed aerodynamics is scientifically invaluable, but perhaps not critical for designing successful ornithopters at a time when most struggle to take-off. Instead, sizing an ornithopter in terms of gross design parameters such as wing span, weight, and flapping frequency is more critical for take-off. The design methodology introduced here explains how one can transform successful designs to meet other mission perspectives. These designs can then enable flight studies that can advance our understanding of ornithopters versus Ro-UAS and FW-UAS to better appreciate their unique advantages.

Amongst successful flappers, there are three main archetypes as shown in Fig. 26.33. Historically, most flappers have relied on variants of a four-bar mechanism to generate the flapping motion which generates lift. One example of this is the Delfly family of ornithopters, which are capable of both fast forward flying and hover using this approach (VIDEO 493). A recent design which demonstrates both prolonged hovering flight and maneuverability, although lacks the ability to fly fast forward, is the Aerovironment

Nano-Hummingbird [26.51]. The Nano-Hummingbird uses a flapping mechanism composed of rollers and strings, while still using a geared down motor to provide power at the right frequency. Additionally, the wings provide control, rather than traditional tail control surfaces. Another more modern development is centimeter scale ornithopters which use piezoelectric actuators to generate flapping motion and control such as the Harvard Robobee [26.52] and the Berkeley Micromechanical Flying Insect. These are capable of tethered flight only, because no batteries exist that can supply high enough power in an enough lightweight package.

Despite the differences in design, these flappers share common trends in parameters, as shown in Fig. 26.34. To design a functional ornithopter, we start with a desired mission such as surveillance, search and rescue, or military applications. The mission determines an appropriate wingspan, and also determines a minimum time for task completion. Figure 26.34 shows that empty weight (mass without battery) follows an exponential pattern with wingspan, especially over the mid-range of wingspans. The main observation is that the power defining scale is not 3, but approximately 1.5. This may be because significant portions of the mass of smaller ornithopters comes from electronics, gearboxes and actuators, whose masses are not dependent on wingspan. Additionally, required flapping frequency decreases with wingspan, enabling an approximation of required flapping frequency based on wingspan that works well for all sizes of ornithopters, as expected using scaling relations.

Using initial design parameters from a successful ornithopter, we can design another ornithopter that is also capable of flapping flight using scaling relationships of geometry, fluid mechanics, and battery physics [26.27]. We need to decide on design parameters for the new flapper, including the wingspan b , weight W , aspect ratio Λ , and battery weight W_{batt} . Here, the aspect ratio is wingspan divided by chord length, as these are both easily measured design parameters. Example of initial parameters for the Delfly II are: $b_1 = 28$ cm, $m_1 = 16$ g ($W = \text{mg}$), $\Lambda_1 = 3.5$, $f_1 = 14$ Hz, $P_1 = 1.4$ W, $W_{\text{batt},1} = 2.7$ g, $t_1 = 15$ min. Initial design parameters are denoted with subscript 1; while new design parameters are denoted with subscript 2. Using the curve fitted through successful ornithopters as shown in Fig. 26.34, one can make an initial approximation of empty weight. First, we can calculate the wing area, A_{fl} , of the new flapper and the old flapper using the same equation for each

$$A \propto \frac{b^2}{\Lambda}. \quad (26.94)$$

Fig.26.34a,b Current ornithopter trends of empty mass and flapping frequency with changes in wingspan. **(a)** The empty mass of successful ornithopters does not scale with wingspan cubed, but with wingspan to the power 1.5 ($R^2 = 0.79$). The power law predicts the approximate masses effectively in the 10–50 cm wingspan range, while it overestimates the mass for those with wingspans below 10 cm. The curve to the third power consistently underestimates the unloaded masses of current ornithopters. **(b)** To support the weight of the ornithopter, flapping frequency needs to increase inverse to wingspan for smaller wingspans. Ornithopters in **(a)** fly freely and have a flight time of at least one minute. The Micromechanical Flying Insect and Harvard Robobee follow the same trend line for flapping frequency as larger ornithopters; even though they fly tethered (they would need to flap faster with batteries onboard). The relationship here fits a power curve with the exponent equal to -1.01 with $R^2 = 0.96$. Abbreviations are as follows: MFI – Berkeley Micromechanical Flying Insect; HMF – Harvard Robobee; KU1,2,3,4 – Konkuk University ornithopters; DFI,II,M-Delfly I,II and Micro; Nano – Aerovironment Nano-Hummingbird; UMD SB, JB, BB – University of Maryland Small Bird, Big Bird, Jumbo Bird; AM – Brian’s Ornithopter; uB3 – NiCad powered Caltech Microbat

In hovering or steady forward flight, it is reasonable to assume that weight is proportional to lift

$$W \propto \frac{1}{2} c_L \rho V_t^2 A_{fl} \quad (26.95)$$

We assume that c_L (lift coefficient), ρ (density,) and g (gravitational acceleration) are constant [26.49], which is reasonable for flights on earth at low altitudes. Then, rearranging produces the following relationship between forward velocities, V_t

$$V_{t,2} = V_{t,1} \sqrt{\frac{W_2 A_{fl,1}}{W_1 A_{fl,2}}} \quad (26.96)$$

We can then assume that the advance ratio J is constant for both vehicles, which is a reasonable approximation for ornithopters with similar wing kinematics, shape, and deformation. The advance ratio J is the ratio of maximum forward speed to wingtip speed

$$J = \frac{V_t}{4f\Phi R} \quad (26.97)$$

Since wingspan is twice the radius, and we can use the assumption that J is constant to obtain the following relationship for flapping frequencies

$$f_2 = \frac{V_{t,2}}{V_{t,1}} \frac{b_1}{b_2} \frac{\Phi_1}{\Phi_2} f_1 \quad (26.98)$$

Then, assuming that flapping amplitude, Φ is constant between the two designs (reasonable for designs that follow the same parameters and keep the same gear-boxes) we can simplify the relationship for flapping frequencies

$$f_2 = \frac{V_{t,2}}{V_{t,1}} \frac{b_1}{b_2} f_1 \quad (26.99)$$

The required power to fly is proportional to the weight and flight speed

$$P \propto mgV_t = WV_t \quad (26.100)$$

Thus, we can calculate the power required of the new flapper relative to that of the old flapper

$$P_2 = P_1 \frac{V_{t,2}}{V_{t,1}} \frac{W_2}{W_1} \quad (26.101)$$

Using the power calculated above, the flight time can be estimated as

$$t = \frac{C_{LiPo} U_{LiPo}}{P} m \quad (26.102)$$

in which $U_{\text{LiPo}} = 3.7 \text{ V}$ for a LiPo battery, and where, as in Fig. 26.35, the capacity can be approximated as

$$C_{\text{LiPo}} = m_{\text{batt}} k_{\text{batt}}. \quad (26.103)$$

From the scaling equations (particularly (26.101) and (26.102)), we can produce a set of graphs as in Fig. 26.36, allowing us to use the wingspan and flight time to design a scaled ornithopter. Beginning with the approximate wingspan and flight time desired, we use Fig. 26.36a to choose the appropriate battery mass. An increase in wingspan creates the option for heavier batteries and an increase in flight time as does an increase in battery mass. The wingspan and battery mass specify the required flapping frequency. This allows us to choose a motor and gear ratio. If this turns out to be impractical with available components, we can adjust parameters and iterate between the equations shown in Fig. 26.36. In general, for an ornithopter with equal mass, increasing the wingspan decreases the necessary flapping frequency. Alternatively, increasing the battery mass to improve flight time also requires increasing flapping frequency, electric power, and current to carry the extra payload. This explains why increasing battery mass beyond empty weight causes little increase in flight time, because the airframe needs to become much stronger at the cost of weight. A penalty in the flight time scaling equation needs to be implemented to correct for the increase in structural weight. The required flapping frequency and battery mass ratio

Fig. 26.35 Battery capacity as a function of mass for many small lithium polymer (LiPo) batteries in the size range ($<10 \text{ g}$) which would be used for ornithopters with 10–50 cm wingspan. The graph shows the technology is linearly scalable. The approximate capacity density of small LiPo cells (3.7 V) is 37 mAh/g

specify the required power. Power increases significantly with wingspan. Additionally, power increases with added battery mass due to the increase in flapping frequency required to lift the larger mass. Finally, we can determine the current the battery needs to supply, which is proportional to the power assuming we use the same kind of battery and efficiency of motor. Iterating between these steps enables finding solutions that best meet the mission specifications. We note that many ornithopters could fly significantly longer by doubling their current battery mass (Fig. 26.36a) at the expense of control response (inertia) and airframe loading.

If flight time needs to increase for a wingspan-constrained ornithopter design, and battery mass and chemistry is already optimized, we should reduce air-

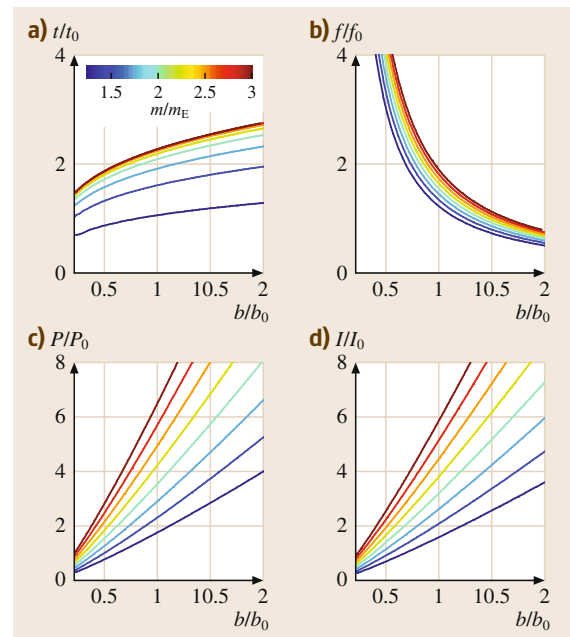

Fig. 26.36a–d These four figures show the effects of changing wingspan and adding battery mass to an ornithopter on the flight time, power consumption, current requirement, and flapping frequency requirement. The value of the empty mass, m_e , is determined using the fitted curve in Fig. 26.34a for each wingspan. The figures are then scaled from the initial reference (Delfly II) whose position is at (1, 1) in each figure. (a) Increasing the battery mass ratio increases the flight time up until the ratio becomes equal to 3. This ignores additional airframe mass needed to carry these batteries. (b) However, increasing the battery mass also increases the required flapping frequency. (c,d) Increasing the frequency also increases the necessary power (P) and current (I). Using these parameters, we can iterate back and forth between the plots until a feasible design is found

Fig. 26.37a–c Changing additional parameters can modify performance of a scaled vehicle. **(a)** Adjusting the flapping amplitude allows the user to change the required flapping frequency to use available motor/gearbox combinations. Generally, larger flapping angles result in increased lift coefficient and decreased drag (after [26.59]). Thus, increasing the amplitude to match it with the motor and gear train can decrease the required power to fly. **(b)** As the aspect ratio increases at a constant wingspan, the wing area decreases, and therefore the flight time decreases while the required flapping frequency (and hence the power and current) increases. **(c)** Flight time decreases with additional payload (weight)

frame mass (Fig. 26.37) and increase wing area [26.49]. Mass can be further decreased by airframe optimization using underutilized aerospace optimization strategies, and by critically reevaluating the payload. Wing area can be increased by decreasing aspect ratio and selecting a biplane instead of a monoplane configuration. Whereas such wing design changes reduce aerodynamic efficiency of the wing, they increase the overall vehicle energy efficiency, and therefore increase flight time. Ornithopters that fly long enough to complete missions are often controlled by low-weight underpowered actuators that sacrifice maneuverability.

To control the ornithopter's flight and to utilize its maneuverability, we need to generate enough control torques with lightweight actuators. Designs optimized for flight time, such as the Delfly, use control surfaces added to the tail in the style of a traditional rudder or elevator. More maneuverable designs use the flapping wings as control surfaces, by changing their angle of attack (Nano-Hummingbird [26.51]) or left versus right wing relative flapping motions (Robobee [26.52]). The two dominant off the shelf actuators are standard servos and magnetic actuators. Standard servos have small electric motors and potentiometers and move to specified positions; while magnetic actuators have a small magnet inside a small coil of wire and apply specified amounts of torque. Magnetic actuators are available at lower masses than servos, which proves critical in optimizing performance of smaller ornithopters. This shows that selecting appropriate actuators involves a tradeoff between flight duration and maneuverability. Ornithopters that are more maneuverable require more powerful and precise servo actuators. The required servo torque of a scaled ornithopter can be estimated assuming isometric scaling: Torque should be proportional to total weight times wingspan, because aerodynamic force is proportional to weight, and arm

length to wingspan. Knowing the required torque, we need to find a servo that can provide it. To reduce trial and error we have plotted current servo data to determine how torque correlates with mass to budget for its weight. The data in Fig. 26.38 shows that torque is proportional to mass squared for current servo technology,

Fig. 26.38 Servo (dots) and actuator (crosses) torques increase with mass. The intensity of dots represents the servo speed, with darker dots representing faster servos (the magnetic actuators do not have speeds shown, as they apply a force rather than specify a position). The servo speed does not correlate strongly with mass, as it is dependent on the motors, gears, and other internal hardware of the servo, as well as the supply voltage. There are magnetic actuators available in the range of 0.8–1.8 g, they are not included here due to lack of data available from manufacturers

while empty ornithopter mass scales with wingspan to the power of 1.5 (Fig. 26.34), so as wingspan increases the actuator mass can become proportionally smaller.

We have demonstrated current design strategies based off scaling successful designs that ensure ornithopters fly. These upgraded *rules of thumb* are powerful because current aerospace design analysis and

optimization techniques for ornithopters lack predictive power and are therefore less informative than estimates based on scaled flying designs. If current designers base their first iteration of new ornithopters on current state-of-the-art ornithopters, the field can progress at a faster pace through successful flight testing of new concepts that meet novel mission criteria.

26.7 System Integration and Realization

Enabling autonomous flights with UAS incorporates solving many challenges. This requires an interdisciplinary approach, bringing together expertise from many different fields. As shown in Fig. 26.39, knowledge in the field of aircraft design, as detailed in this chapter, is required, as well as in many fields of engineering and robotics.

26.7.1 Challenges for Autonomous UAS

Given the agility of UAS and their strict limitations on weight and power consumption, the choice of sensors, processors, and algorithms impose great technical and scientific challenges. Also, major differences exist between ground vehicles and UAS – sensors and algorithms that work well on ground vehicles cannot simply be applied on UAS due to inherent challenges.

Limited Payload and Power Supply

Weight and size restrictions require that lightweight sensors have to be used, usually at the cost of having noisier and less accurate data. These limitations also restrict the choice of onboard computers being used to

process information from the sensors. Thus, algorithms need to cope with such data to achieve robust estimates, while having limited computational power. As a reference, the take-off weight of a commonly used small multirotor UAS (e.g., shown in Fig. 26.40) is 1.5 kg, including 0.5 kg of payload, while the flight autonomy is approximately 15 min. For this class of UAS, approximately 100 mW are required per 1 g additional take-off weight for hovering – a fact that has to be considered even for mounting small additional payload. Detailed studies of take-off weight, payload, and flight time of such systems can be found in [26.60].

Degrees of Freedom

Compared to typical ground vehicles, there are two additional degrees of freedom (DOF) for the vehicle's attitude (pitch and roll angle) as well as one additional degree of freedom for the altitude, that need to be estimated and controlled. This requires state estimation, control, and planning to be performed in full 6-D space, and without simplifying assumptions.

Under-Actuated Systems

The types of UAS studied here are usually under-actuated, as there are less control inputs available than DOF. As a result, the attitude has to be changed for many maneuvers. This in return changes the field of view of onboard sensors interacting with the UAS' environment like cameras, or distance sensors.

Constant Motion and Inherent Instability

UAS cannot simply stop to acquire sensor readings, when state estimation is delayed or contains high uncertainty. While waiting for measurements or re-evaluation of uncertain state estimates, the vehicle continues moving and further falsifies these estimates.

26.7.2 Levels of Autonomy

We classify levels of autonomy and interaction with the pilot or operator into three categories: Manual flight, semiautonomous and autonomous. Industry and the re-

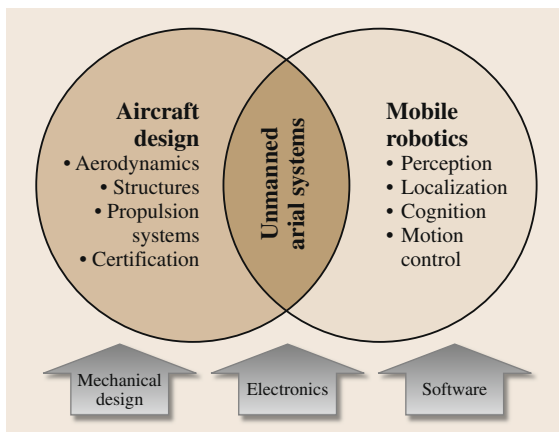

Fig. 26.39 UAS design and research is interdisciplinary as challenges from both aircraft design and mobile robotics are combined

Fig. 26.40 Multi-rotor UAS and its main components (after [26.60])

search community have made great progress toward semiautonomous flights, while there are still many open questions and research topics for truly autonomous operation.

Manual Flight

We refer to this mode when operation of the UAS requires pilot skills. A remote-pilot has to handle attitude dynamics and throttle/thrust in a way such that the UAS remains in a stable state. That is, the pilot cannot leave the hands off the remote control. This also means that line-of-sight has to be maintained up to a distance where the pilot can observe the state of the UAS properly. Piloting may be aided by a stability augmentation system (SAS), like rate stabilization commonly used on fixed wing aircraft, or attitude control commonly used on multirotor UAS.

Semiautonomous (Automatic)

This flight mode does not require piloting skills anymore, which is why we refer to a pilot rather than an operator. Onboard sensors and algorithms are in charge of stabilizing the UAS, such that the operator can leave the hands off the remote control and the UAS remains in a stable state, waiting for input such as waypoints or desired velocities. However, it is still the full responsibility of the operator to find feasible paths, safely navigate around obstacles and to interact with other air traffic. This requires line of sight to be maintained, however, first-person view could be thought of,

Fig. 26.41 Components for an autonomous UAS

as long as legal requirements are fulfilled. Examples for such modes are off-the-shelf multirotor UAS [26.61] equipped with GPS sensors or small fixed-wing aircraft [26.62] used for surveying.

Autonomous

Full autonomous mode relaxes the constraints from semiautonomous or automatic mode. Only mission goals are set, or high-level task allocation is handled by the operator, while the UAS navigates through the environment safely by itself. This includes global path planning, collision avoidance with both static and dynamic objects and replanning where necessary. The main idea is that the UAS can be *left alone* while performing the task at hand, and, in case, warns the operator ahead of time if intervention becomes necessary.

26.7.3 UAS Components

Autonomous UAS require numerous components from various fields, which need to be carefully designed in order to address the challenges detailed above. We highlight important design considerations of building blocks first, and show implementation aspects for real systems. Figure 26.40 shows the components for a commonly used multirotor UAS.

Components for Autonomous Flights

The levels of autonomy defined in Sect. 26.7.2 require several components to be designed and to work with each other. These components are shown in Fig. 26.41 and are described in the following:

Perception and State Estimation. Perception for autonomous UAS mainly involves both localization of the UAS and sensing of its environment. For localization, commonly used satellite-based localization systems such as GPS (GLONASS or GALILEO in the future) may not be accurate enough, especially during tasks that involve operation in close proximity to (man-made) structure, and certainly not indoors. Di-

rect view to satellites is obstructed in these cases, compromising localization accuracy. Also, it may be considered whether sole reliance on these services is acceptable, as authorities may deteriorate the accuracy on purpose (*selected availability*). Thus, additional sensors such as cameras or laser-range finders should be used onboard **UAS** in combination with simultaneous localization and mapping (**SLAM**), or visual or laser odometry algorithms, yielding additional localization information [26.63–67].

Another important requirement to enable autonomous flights on the levels defined above, is sensing or reconstruction of the environment in order to navigate around obstacles, and for sense-and-avoid maneuvers with other air traffic. Obstacle sensing is especially important when navigating close to terrain at low altitude. Satellite-based navigation in combination with terrain maps may not be accurate enough, outdated, and cannot handle dynamic obstacles. Again, onboard sensors such as cameras, laser-range finders, or even radar, in combination with appropriate algorithms need to be used to overcome the limitations mentioned before [26.68, 69].

Having information from a multitude of sensors, from IMU over cameras to satellite-based, intelligent sensor fusion methods are required, taking all information into account and yielding a best estimate of the state of the **UAS** and its environment. As such, perception and state estimation are building blocks, providing essential information to the components described in the following.

Control. As **UAS** typically present highly dynamic uncertain flight behavior, appropriate and robust control techniques are required across all levels of autonomy. This ranges from **SAS** used for supporting the pilot during manual operation, to higher level control such as waypoint following, and more advanced techniques such as trajectory tracking, and may include handling of failure situations. Cascaded control structures are commonly used for this task [26.70]: inner- or low-level control loops stabilize attitude dynamics (these may be cascaded already), while outer- or high-level control loops stabilize translational dynamics (velocity or position). Employed control approaches range from simple P(I)D structures to more advanced techniques like model predictive control (**MPC**) [26.3]. During waypoint following, specified waypoints have to be reached and via-points have to be passed, while the velocity and attitude profile is left to the controller to optimize. For trajectory tracking in contrast, a tracking controller [26.71] has to follow specific profiles for position and attitude dynamics. These profiles are usually planned with approaches presented below,

and yield more smooth paths than simple waypoint following.

Planning. Planning in the context of **UAS** depicts the process of planning appropriate waypoints or dynamic trajectories for a **UAS** depending on the mission at hand. This involves the latter two levels of autonomy described in the previous section. Requirements range from (dynamic) obstacle avoidance, taking obstacles and the dynamics of the **UAS** into account, to more sophisticated complete mission plans [26.72]. While taking into account vehicle dynamics is a straightforward choice, additional constraints such as quality of state estimation along a path, or battery endurance may have to be considered as well. Furthermore, there may be additional objectives like area covered or, for instance, energy optimizations for solar airplanes in order to stay airborne 24 h or longer.

While analytic approaches [26.73] can be used for simple planning tasks, random sampling-based planners [26.74–76] dominate the literature in the area of path planning for **UAS**, due to their ability to cope with nonlinear vehicle dynamics and high-dimensional state spaces. Based on these planners, a number of successful approaches exist for **UAS**, even taking into account localization uncertainty [26.4, 77–79].

Communication. Communication can be thought of the *glue* between the components mentioned above. While components have to communicate onboard across multiple computation devices, there is also the need of communication with a ground station, or with the operator remote control device, via radio-links. Here, the requirements in terms of range, delay, and transmission rate (commonly referred to as *bandwidth*) can vary greatly and should be tailored to the application: computationally heavy tasks, being offloaded to a ground station require high-bandwidth connections, where either WiFi (IEEE 802.11n or IEEE draft 802.11ac) or ultra wide band (**UWB**) techniques can be applied. However, a reasonable maximum range is in the order of 100 m. More autonomy means also less dependence on radio-links and realtime constraints. Missions involving larger distances have to rely on longer range radio-links, even up to satellite links, but at the expense of bandwidth and delay or significant weight and power requirements. That radio-links should never be used inside any (real-time) critical control loops, goes without saying.

Integration Onboard **UAS**

The components identified above have different requirements in terms of real-time constraints and computational complexity. Instead of real time, it is more

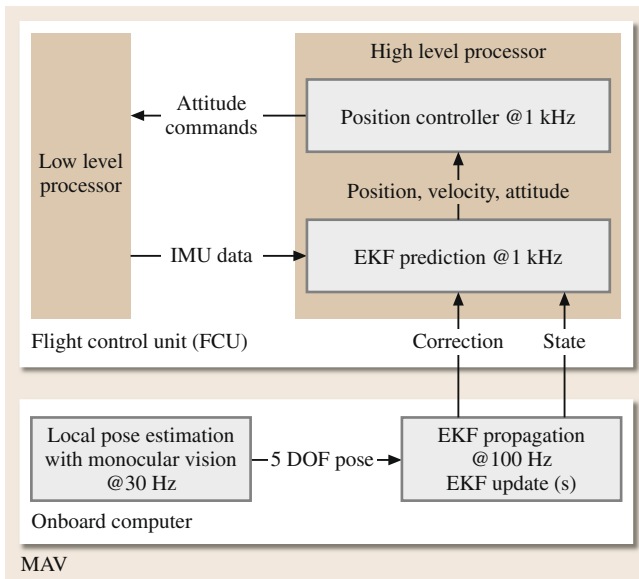

Fig. 26.42 Example implementation of flight-relevant components onboard a multirotor UAS. All time-critical tasks such as control and the prediction part of an extended Kalman filter (EKF) are performed on real-time microcontroller hardware, while computationally more demanding, but less time-critical, tasks (visual localization, EKF update) are processed on the onboard computer using a standard operating system

appropriate to consider that a task has to be completed *in time*. As an example, vehicle *control* tasks have to be computed within a few milliseconds, but these task are

computationally less complex. *Path planning* in contrast is fairly complex, but it is usually perfectly fine if a path is computed within seconds, since planning horizons span much longer time. *Perception* and parts of *state estimation* lie in-between and need computation times in the order of tens of milliseconds. This defines how, and on which computation devices these components should be implemented. An example for a multirotor UAS is shown in Fig. 26.42. The microcontrollers on the flight-control-unit (FCU) are closest to inertial sensors and actuators, but least powerful. Control loops and the prediction parts of the state estimator are implemented here, running at guaranteed rates on a real-time operating system, or even without. This relaxes real-time constraints on the onboard computer, which can compute demanding tasks such as visual localization and update steps for state estimation. Local planning tasks are computed here as well, while less critical parts can be offloaded to a ground station.

Application Related Payload

While there is a set of sensors required to enable autonomous navigation, which are referred to as navigation sensors, additional sensors, or payload in general, need to be considered in the design phase. Not only in terms of payload, i.e., weight, but also such that the UAS is kept balanced. Furthermore, it has to be guaranteed that the additional payload does not interfere (electromagnetically) with components in the critical stabilization loop. Applications and their required sensors are detailed in the next section.

26.8 Applications of Aerial Robots

From an application perspective, one may distinguish between UAS that mostly operate as remote controlled or semiautonomous systems (typically referred to as drones) and intelligent systems, robots that present advanced levels of autonomy. Drones are essentially tele-operated aircraft or systems capable of tracking predefined trajectories while they further integrate onboard sensors to provide situational awareness. Most often such situational awareness is visual (using optics) but can also include meteorological and environmental tasks like hurricane-monitoring and chemical plume detection. As such, most drones fly high with a predetermined and structured flight plan and mission profile. Drones will continue to be valuable assets and as featured in daily media headlines world-wide, positively impact both civilian and military missions.

Nowadays, a constant trend is to develop aerial robots of advanced intelligence. Machine cognition,

perception and vehicle control algorithms work in concert to perform applications that go beyond just situational awareness. Reaching new levels of autonomy, these robots are designed to handle unforeseen events, interact with their environment, and adapt to a broad range of scenarios. In essence, drones were in their vast majority *passive*, providing *eyes* on scene whereas modern aerial robots tend to become *active*, allowing their users to *engage* the scene, act *autonomously* and possibly *interact* with surroundings. Figure 26.43 presents indicative examples of current and emerging applications.

26.8.1 Demonstrated Applications of UAS

The Handbook's first edition listed eight categories of *possible* applications. Since then, all these applications have been realized, albeit with various levels of ma-

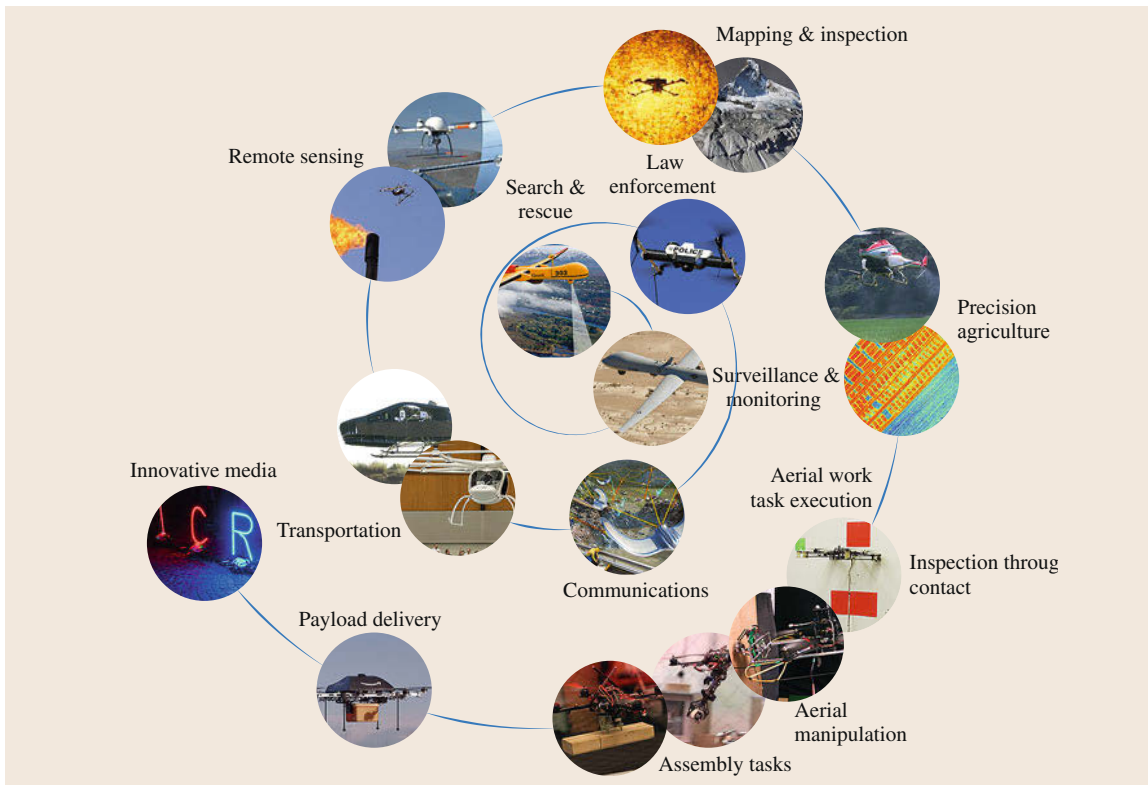

Fig. 26.43 Indicative demonstrated and emerging applications of aerial robotics

turity. UAS (both drones and aerial robots) have been deployed in:

1. Remote sensing
2. Disaster response
3. Surveillance
4. Search and rescue
5. Image acquisition
6. Communications
7. Transportation
8. And payload delivery.

The first five categories broadly fall into the area of reconnaissance, surveillance, and target acquisition (RSTA). Drones have continued to successfully perform RSTA-based tasks like volcanic sampling, damage assessment, border patrol, and cinematography. In contrast, the latter three categories are being realized with advanced aerial robots. Equipped with computational intelligence aerial robots can flock. Aerial robots can also airlift, maneuver and interact in near-Earth environments like in-and-around buildings, forests, caves and tunnels. As such current trends in aerial robotics push the application envelope beyond RSTA. The eight categories are now revisited with context on the ex-

pected breakthroughs to come while the topic of visual inspection for industrial purposes is separately discussed:

- *Remote sensing*: Drones are already used for pipeline spotting, power line monitoring, volcanic sampling, mapping, meteorology, geology, agriculture and unexploded mine detection. Advanced aerial robots will be able to conduct pipeline risk assessment and repair, power line maintenance, real-time mapping, crop care and mine defusing.
- *Disaster response*: Drones are also used for chemical sensing, flood monitoring, and wildfire management. Advanced aerial robots will be able to conduct infrastructure repair, flood mitigation, and wildfire fighting.
- *Surveillance*: Drones are employed for law enforcement, traffic monitoring, coastal and maritime patrol, and border patrols. Advanced aerial robots will be able to accomplish tasks like crowd control, traffic redirection, and inspection of maritime and trucking containers.
- *Search and rescue*: The vision of using drones for search and rescue operations within low-density or hard-to-reach areas has already become a reality.

Advanced aerial robots will be able to go beyond casualty extraction by assessing care and delivering first-aid support.

- **Visual inspection:** For quite some time, drones are utilized to provide direct visual feeds to ground operators inspection industrial and civil structures. Future aerial robots will be able to act as a new high fidelity autonomous inspection tools that could also be capable of conducting maintenance work tasks.
- **Transportation:** Drones are already used for small- and large-cargo transport, and possibly passenger transport. Advanced aerial robots will be able to conduct in-flight refueling of other aircraft, pick-up and drop-off of cargo as well as loading and extraction of casualties.
- **Communications:** The use of drones as permanent or ad hoc communication relays for voice and data transmission, as well as broadcast units for television or radio is currently a reality. Advanced aerial robots will be able to conduct perch-and-stare to serve as *bug on the wall* listening devices, perch-and-stare to harvest energy from power lines, flocking to establish networks especially in areas with degraded communications.
- **Payload delivery:** Drones are already employed for firefighting or crop dusting. Advanced aerial robots will be able to accomplish dexterous manipulation of payloads like tools for repairing structures, delivering, and insertion of logistics as well as handling crops.
- **Image acquisition:** Cinematography or real-time entertainment is another relatively established use-case of drones. Advanced aerial robots will be able to conduct acting as *pixels* and operate in formation flight to serve as physical displays in the air.

26.8.2 Current Applications and Missions

Since the Handbook's first edition, media headlines continue to document [UAS](#) and their impact in all the aforementioned application categories. No longer are such applications notional but are rather considered as routine. The following provides recent state-of-the-art examples in each category to underscore this message.

Drone usage for [RSTA](#)-based military operations is routine. Tracking targets and, in growing instances, destroying them, is commonly performed. But also non-military missions in remote sensing, disaster response, and surveillance are becoming routine. Beyond image acquisition, drones are routinely used to gather meteorological data. [NASA](#) and [NOAA](#) regularly deploy drones for real-time monitoring of hurricanes. On-board sulfur dioxide sensors gather airborne samples from volcanic plumes. Drones are frequently deployed

after disasters: in Fukushima (2011) and Hurricane Sandy (2012) aerial images were gathered to assess building damage. Monitoring of maritime piracy and cartel drug-trafficking also underscore the usefulness of drones to persistently survey using high-definition cameras and night vision systems.

Currently, drones are deployed to open and/or restricted areas where airborne collision risk is reduced. The need for situational awareness will however continue to be fulfilled by [UAS](#). The demand for more data will push the development of newer drones. As such, well-known and cutting-edge aerodynamic design principles will be applied so that [UAS](#) fly longer and farther and incorporate different flight modalities like vertical take-off and landing ([VTOL](#)). Sensor suites will also grow in sophistication to collect higher-resolution and/or multispectral data. Propulsion technologies will also be engineered to enable [UAS](#) to carry more sensors. The net effect is that as missions become more routine and frequent, the variations of drones and their performance will grow to keep up with expanding [RSTA](#)-based needs.

26.8.3 Aerial Robots: Emerging Categories

The road ahead is full of challenging emerging applications that will benefit from the utilization of aerial robotic technologies. This is especially the case when one considers near-Earth environments like in-and-around buildings, through forests and down tunnels and caves. Beyond [RSTA](#), such environments provide opportunities for aerial robots to dexterously interact with objects. Today's drones release retardants over wildfires but tomorrow's aerial robots would attach hoses and breach walls for firefighting. Interaction demands advances in areas like aircraft design (flight modalities, payload capability), algorithms (perception, control, motion planning, and grasping) and manipulators (arms and end-effectors). The latter two areas overlap with the greater domain of robotics research. As deeper understanding and realizations develop, the application space, demand and impact of aerial robots will grow even greater. In the following, a brief overview of exciting emerging applications will be listed.

Assembly Work Task Execution

One notional concept employs aerial robots to assembly physical structures. Such assembly pushes the boundaries of the categories of transportation and payload delivery. Labs like those of University of Pennsylvania [26.80], Switzerland (ETH Zurich [26.81]) have used gripper-mounted quadrotors to illustrate proof-of-concept. Demonstrations include the pickup and drop-off of workpieces to defined locations. These

workpieces self-connect using magnets or premachined joints but illustrate capabilities to coordinate multiple aircraft, mitigate disturbances like ground effect, sense and map, and execute agile maneuvers. Groups at Drexel, Twente, Seville, and Yale are equipping rotorcraft robots with manipulators to illustrate more dexterous tasks like inserting, screwing, and removing workpieces. Assembly and in general physical work-task execution will find applications in categories like disaster response (repairing structures) and remote sensing (inserting sensors).

Inspection Through Contact

Inspecting containers at docks, ships, and border crossings is a daunting task. Sensor technology is advancing to look inside such containers. However, dexterous aerial robots that can open hatches and trunks could also yield many applications. Inspection as an emerging category can employ aerial robots to physically interact with structures. Aerial robots can physically probe bridges, pipelines, and power lines to repair and replace parts. Interactive inspection could emerge to applications like crop handling and mine defusing. Labs like those of ETH Zurich [26.82] and the University of Bologna [26.83] have presented relevant results in the topic.

Innovative Media

Both the number of vendors and affordability of rotorcraft robots have increased since the Handbook's first edition. In mid-2000, it was not surprising to see a commercial quadrotor costing 40 000 USD. Today, there are dozens of companies providing robotic rotorcraft ranging in price (hundreds to under 10 000 USD), size (from pucks to bike wheels) and configurations (mono, co-axial, and multirotor). Such range will likely yield innovative and entrepreneurial applications.

The Firefly project at the MIT SENSEable Lab perhaps best illustrates the notion of coordinating multiple aerial robots to display images. Each aerial robot acts as flying *pixel* and maneuver into position to form 2 or 3-D images. Beyond visual and dynamic art, such capabilities could yield airborne displays for tasks like crowd control, traffic redirection and SOS signals. Airborne displays could also expand creative expression to enhance concerts, advertise at stadiums, and inform audiences.

Autonomous Structural Inspection and 3-D Reconstruction

From the perspective of the role of aerial robotics in accelerating growth, mapping of areas, structural inspection of buildings and infrastructure as well as recognition of objects or areas of interest is among the most important application fields. Aerial robots have

achieved great milestones in such scenarios. Among others, recently researchers managed to extract a high-fidelity 3-D model of the Swiss mountain top Matterhorn utilizing a small FW-UAS and sophisticated robotic vision techniques [26.84], other efforts led to the inspection of a real power plant boiler using a multirotor vehicle and tightly integrated visual-inertial algorithms [26.85], while in terms of industrial adoption aerial robots have provenly minimized the inspection times of power infrastructure [26.86] and are often used in combination with geographic information system (GIS) data [26.84]. It is worth noting that some of the largest asset owners and service providers in the field of civil infrastructure and civil engineering works have shown interest and participate in large consortia that aim to make such aerial robotic technologies an integral and game-changing factor of how things are done (see e.g., Petrobot Project [26.87], ARCAS: Aerial Robotics Cooperative Assembly System [26.88], EuroC: European Robotics Challenges [26.89], ARGOS Challenge [26.90]).

Precision Agriculture

Precision agriculture is considered to be among the fields where the use of aerial robots may become a key factor boosting growth and improving the production quality. The Japanese farming sector has historically been in a position to lead the relevant research efforts with successful designs like the Yamaha RMAX being extensively used for monitoring as well as spraying operations [26.5]. Already in December 2002, 1687 aerial robots were used in Japan to conduct precision agriculture operations. However, current research contributions and pioneering technology early adopters have opened an even more promising channel for the widest possible utilization of aerial robotic technologies for the benefit of agriculture production. Mainly through the use of miniaturized aerial robotics at farms of smaller scale and via the integration of advanced multispectral perception sensors (i.e., NDVI) [26.91], accurate mapping and analysis regarding the quality of the field, the level of plant growth and existence of diseases becomes possible. Such technologies are expected to become a critical tool to optimize and enhance agricultural services. Furthermore, manipulators-equipped aerial robots will be able to autonomously physically act based on their perception of the field and minimize the time and effort required for several agriculture services and tasks.

26.8.4 Open Issues

Emerging categories underscore both the distinction between more traditional drones and emerging aerial

robotic technologies as well as how much further the state-of-the-art has to be pushed. Clearly, today's **UAS** have limited payloads but adding manipulators goes beyond lift issues. When interacting with objects, aerial robots must handle reaction forces and torques. Understanding such reactions remains an open issue. However, both space and underwater roboticists have looked at dexterous manipulators for tasks like satellite repair and turning valves on ocean-based oil rigs. As research clarifies this issue and as lift capacities increase, dexterous aerial robots will be realized.

Airspace access is an often cited issue that may limit aerial robot development and vast utilization. A US congressional bill was passed in 2012 that sets requirements for **UAS** to fly in the national airspace by 2015. This has also sparked competition among a dozen or

so states to establish **UAS** flight testing sites. In Europe, similar events have happened and there are **UAS** test sites in places like Finland (Kemijärvi), Sweden (NEAT), and Wales (Parc Aberporth).

Lastly, somewhat ironic is that today's unmanned drones require a crew of highly skilled operators. In the case of some Predator missions, crew sizes can be up to a dozen people. Also ironic is that human error is the most cited cause for drone accidents. As the number of **UAS** in the national airspace increases, the need for even more operators will also grow. This has the potential to raise the risk of **UAS**-related accidents. The issues of effective **UAV** pilot training, certifying operators, handling emergency landings, and sharing airports with manned aircraft will also emerge as pressing ones.

26.9 Conclusions and Further Reading

Design of aerial robots requires background knowledge in a multitude of subjects, from aerodynamics to dynamics, control, and system integration: we have overviewed the relevant basics along with analytical tools and guidelines to go through the stages of designing, modeling, and setting up operation of various types of unmanned aerial systems (**UAS**). An emphasis was given on custom tailoring a system to a specific application, in order to

optimally meet related requirements in terms of endurance, range, agility, size, complexity, as well as from a system integration point of view. The compilation at hand shall serve as a starting point, further motivating the reader to study the various fields with their related literature, ranging from aircraft and system design to the classical autonomous robotics challenges involving perception, cognition and motion control.

27. Micro-/Nanorobots

Bradley J. Nelson, Lixin Dong, Fumihito Arai

The field of microrobotics covers the robotic manipulation of objects with dimensions in the millimeter to micron range as well as the design and fabrication of autonomous robotic agents that fall within this size range. Nanorobotics is defined in the same way only for dimensions smaller than a micron. With the ability to position and orient objects with micron- and nanometer-scale dimensions, manipulation at each of these scales is a promising way to enable the assembly of micro- and nanosystems, including micro- and nanorobots.

This chapter overviews the state of the art of both micro- and nanorobotics, outlines scaling effects, actuation, and sensing and fabrication at these scales, and focuses on micro- and nanorobotic manipulation systems and their application in microassembly, biotechnology, and the construction and characterization of micro and nanoelectromechanical systems (MEMS/NEMS). Material science, biotechnology, and micro- and nanoelectronics will also benefit from advances in these areas of robotics.

27.1 Overview of Micro- and Nanorobotics

Progress in robotics over recent years has dramatically extended our ability to explore, perceive, understand,

and manipulate the world on a variety of scales extending from the edges of the solar system, to the bottom

of the sea, down to individual atoms (Fig. 27.1). At the lower end of this scale, technology has been moving toward greater control of the structure of matter, suggesting the feasibility of achieving thorough control of the molecular structure of matter atom by atom, as *Feynman* first proposed in 1959 in his prophetic article on miniaturization [27.1]:

What I want to talk about is the problem of manipulating and controlling things on a small scale. . . I am not afraid to consider the final question as to whether, ultimately – in the great future – we can arrange the atoms the way we want: the very atoms, all the way down!

He asserted that

At the atomic level, we have new kinds of forces and new kinds of possibilities, new kinds of effects. The problems of manufacture and reproduction of materials will be quite different. The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom.

This technology is now labeled *nanotechnology*.

The *great future* of *Feynman* began to be realized in the 1980s. Some of the capabilities he dreamed of have been demonstrated, while others are being actively pursued. *Feynman* foresaw the possibility of employing a microrobotic manipulator (*a master–slave system*) for bottom-up manufacturing (manipulation, assembly, etc.) of minute machines; one such device he described as *swallowing the surgeon*, which he attributed to his friend Albert R. Hibbs. He also imagined we could *build a billion tiny factories, models of each other, which are manufacturing simultaneously, drilling holes, stamping parts, and so on* [27.1]. Micro- and nanorobotics research has progressed from these seemingly *far-out* concepts of the 1960s and 1970s to reality when microelectromechanical systems (**MEMS**) began to emerge in the late 1980s. These building blocks took the form of surface-micromachined micromotors and microgrippers made of polysilicon fabricated on a silicon chip [27.2]. In the late 1980s and early 1990s, more concrete suggestions on how one could realize **MEMS**-based microrobotic devices using such micromotors as well as potential applications were published [27.3, 4]. Today, a variety of microrobotic devices are enabling new applications in various fields.

In industry, interesting areas for microrobotics include assembly [27.5, 6], characterization, inspection and maintenance [27.7, 8], microoptics (positioning of microoptical chips, microlenses and prisms) [27.9], and microfactories [27.10]. Many of these applications require automated handling and assembly of small parts with accuracy in the submicron range.

Other important fields include biology (manipulation, capturing, sorting and combining cells [27.11]) and medical technology [27.12, 13]. In surgery, the use of steerable catheters and endoscopes is very attractive and the development of increasingly small microrobotic devices is rapidly progressing. Wireless untethered microrobots that will explore and repair our bodies (*swallowing the surgeon*) appear to be simply a matter of time. In fact, endoscopy using wireless capsules (camera pills) are already on the market and allow for endoscopic imaging of the entire gastrointestinal tract [27.14], something currently not possible using standard scopes. Magnetic steering or crawling-type motions serve as promising ways for such devices to locomote in a controlled fashion [27.15]. Doctors could steer pill-mounted cameras and other actuators to areas of interest for visual investigation and biopsies beyond the range of current endoscopes.

Nanorobotics represents the next stage in miniaturization for maneuvering nanoscale objects. Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size, i.e., nanorobots, and large robots capable of manipulating objects that have nanometer dimensions with nanometer resolution, i.e., nanorobotic manipulators. The field of nanorobotics brings together several disciplines, including nanofabrication processes used for producing nanoscale robots, nanoactuators, nanosensors, and physical modeling at nanoscales. Nanorobotic manipulation technologies, including the assembly of nanometer-sized parts, the manipulation of biological cells or molecules, and the types of robots used to perform these types of tasks also form a component of nanorobotics.

As the 21st century unfolds, the impact of nanotechnology on the health, wealth, and security of humankind is expected to be at least as significant as the combined influences in the 20th century of antibiotics, the integrated circuit, and human-made polymers. For example, N. Lane stated in 1998, [27.16]

If I were asked for an area of science and engineering that will most likely produce the breakthroughs of tomorrow, I would point to nanoscale science and engineering.

The great scientific and technological opportunities nanotechnology presents have stimulated extensive exploration of the nanoworld and initiated an exciting worldwide competition, which has been accelerated by the publication of the *National Nanotechnology Initiative* by the US government in 2000 [27.17]. Nanorobotics will play a significant role as an enabling nanotechnology and could ultimately be a core part of

Fig. 27.1 Robotic exploration at micro- and nanometer scales

nanotechnology if *Drexler's* machine-phase nanosystems based on self-replicative molecular assemblers via mechanosynthesis can be realized [27.18].

By the early 1980s, scanning tunneling microscopes (STMs) [27.19] radically changed the way in which we interacted with and even regarded single atoms and molecules. The very nature of proximal probe methods encourages the exploration of the nanoworld beyond conventional microscopic imaging. Scanning probes now allow us to perform *engineering* operations on single molecules, atoms, and bonds, thereby providing a tool that operates at the ultimate limits of fabrication. They have also enabled exploration of molecular properties on an individual nonstatistical basis.

STMs and other nanomanipulators are nonmolecular machines that use bottom-up strategies. Although performing only one molecular reaction at a time is obviously impractical for making large amounts of a product, it is a promising way to provide the next generation of nanomanipulators. Most important, it is possible to realize the directed assembly of molecules or supermolecules to build larger nanostructures through nanomanipulation. The products produced by nanomanipulation could be the first step of a bottom-up strategy

in which these assembled products are used to self-assemble into nanomachines.

One of the most important applications of nanorobotic manipulation will be nanorobotic assembly. However, it appears that, until assemblers capable of replication can be built, the combination of chemical synthesis and self-assembly are necessary when starting from atoms; groups of molecules can self-assemble quickly due to their thermal motion, enabling them to *explore* their environments and find (and bind to) complementary molecules. Given their key role in natural molecular machines, proteins are obvious candidates for early work in self-assembling artificial molecular systems. *Degrado* [27.20] demonstrated the feasibility of designing protein chains that predictably fold into solid molecular objects. Progress is also being made in artificial enzymes and other relatively small molecules that perform functions like those of natural proteins. Several bottom-up strategies using self-assembly appear feasible [27.21]. Chemical synthesis, self-assembly, and supramolecular chemistry make it possible to provide building blocks at relatively large sizes beginning from the nanometer scale. Nanorobotic manipulation serves as the base for a hybrid approach to

construct nanodevices by structuring these materials to obtain building blocks and assembling them into more complex systems.

Despite the claims of many *futurists*, the form nanorobots of the future will take and what tasks they will actually perform remain unclear. However, it is clear that nanotechnology is progressing towards the construction of intelligent sensors, actuators, and systems that are smaller than 100 nm. These nanoelectromechanical systems (NEMSs) will serve as both the tools to be used for fabricating future nanorobots as well as the components from which these nanorobots may be developed. Shrinking device size to these dimensions presents many fascinating opportunities such as manipulating nano-objects with nanotools, measuring mass in femtogram ranges, sensing forces at piconewton scales, and inducing gigahertz motion,

among other new possibilities waiting to be discovered. These capabilities will, of course, drive the tasks that future nanorobots constructed by and with NEMS will perform. NEMS and the components of nanorobots will be the products of nanorobotic manipulation. Large nanorobotic manipulators will be able to shrink in size due to this development, thus enabling nanosized robotic manipulators and other forms of nanorobots. All of these form the scope of the area of nanorobotics.

This chapter focuses on micro- and nanorobotics including actuation, manipulation, and assembly at the micro- and nanoscale. The main goal of these fields of robotics is to provide an effective technology for the experimental exploration of the micro- and nanoworld, and to push the boundaries of this exploration from a robotics research perspective.

27.2 Scaling

27.2.1 The Size of Things

Things we can potentially observe range from 10^{-35} m (the Planck length) to 10^{26} m (the radius of the observable universe). A nanometer, 10^{-9} m, is about ten times the size of the smallest atoms, such as hydrogen and carbon, while a micron is barely larger than the average wavelength of visible light, thus invisible to the human eye. A millimeter, the size of a pinhead, is roughly the smallest part typically fabricated using traditional machining techniques. The range of scales from millimeters to nanometers is one million (Fig. 27.1), which is also about the range of scales in present-day mechanical technology from the largest skyscrapers to the smallest conventional mechanical machine parts. The vast opportunity to make new machines spanning almost six orders of magnitude from 1 mm to 1 nm, is one take on *Feynman's* famous statement, *there is plenty of room at the bottom* [27.1]. If L is taken as a typical length, 0.1 nm for an atom, perhaps 2 m for a human, this scale range in L would be 2×10^{10} . If the same scale range were to apply to an area, $0.1 \text{ nm} \times 0.1 \text{ nm}$ versus $2 \text{ m} \times 2 \text{ m}$, the scale range for area L^2 is 4×10^{20} . Since a volume L^3 is enclosed by sides L , we can see that the number of atoms of size 0.1 nm in a $(2 \text{ m})^3$ volume is about 8×10^{30} , recalling that Avogadro's number $N_A = 6.022 \times 10^{23}$ is the number of atoms in a gram-mole, supposing that the atoms were ^{12}C , molar responding to a density $1.99 \times 10^4 \text{ kg/m}^3$. A primary working tool of the nanotechnologist is facility in scaling the magnitudes of various properties of interest, as the length scale L shrinks, e.g., from 1 mm to 1 nm.

Clearly, the number of atoms in a device scales as L^3 . If a transistor on the micron scale contains 10^{12} atoms, then on the nanometer scale, $L'/L = 10^{-3}$ it will contain 1000 atoms, likely too few to preserve its function.

Normally, we will think of scaling as an isotropic scale reduction in three dimensions. However, scaling can be thought of usefully when applied only to one or two dimensions, scaling a cube to a two-dimensional (2-D) sheet of thickness a or to a one-dimensional (1-D) tube or nanowire of cross-sectional area a^2 . The term *zero-dimensional* (0-D) is used to describe an object small in all three dimensions, having volume a^3 . In electronics, a zero-dimensional object (a nanometer-sized cube a^3 of semiconductor) is called a quantum dot (QD) or *artificial atom* because its electronic states are few and sharply separated in energy, and thus resemble the electronic states of an atom.

27.2.2 Predominate Physics at the Micro- and Nanoscales

The predominate physics at the micro- and nanoscale can be dramatically different from at the macroscale. Surface and intermolecular forces, such as adhesion forces originating from surface tension forces, van der Waals forces, and electrostatic forces, become more significant than volumetric forces such as gravitational forces for objects with sizes well below $1000 \mu\text{m}$ [27.22]. Although the laws of classical Newtonian physics may well suffice to describe changes in behavior down to 10 nm (100 Å), the range of scaling

is tremendous. Therefore, the changes in magnitudes of many important physical properties, such as resonant frequencies, are so great, that completely different applications may appear.

The more challenging question for the nanotechnologist is to understand and hopefully to exploit those changes in physical behavior that occur at the end of the classical scaling range. The *end of the scaling* is the size scale of atoms and molecules, where nanophysics [27.23] is the proven conceptual replacement of the laws of classical physics. Modern physics, which includes quantum mechanics as a description of matter on a nanometer scale, is a very well-developed

and proven subject whose application to real situations is limited only by modeling and computational competence.

In the modern era, simulations and approximate solutions increasingly facilitate the application of nanophysics to almost any problem of interest. Many central problems are already (adequately, or more than adequately) solved in the extensive literatures of theoretical chemistry, biophysics, condensed matter physics, and semiconductor device physics. The practical problem is to find the relevant work, and, frequently, to convert the notation and units systems to apply the results to the problem at hand.

27.3 Actuation at the Micro- and Nanoscales

The positioning of nanorobots and nanorobotic manipulators depends largely on nanoactuators. While nanosized actuators for nanorobots are still under exploration and relatively far from implementation, MEMS-based efforts are focused on shrinking their sizes [27.24]. Nanometer resolution motion has been extensively investigated and can be generated using various actuation principles. Electrostatics, electromagnetics, and piezoelectrics are the most common ways to realize actuation at nanoscales. For nanorobotic manipulation, besides nanoresolution and compact sizes, actuators generating large strokes and high forces are best suited for such applications. The speed criteria are of less importance as long as the actuation speed is in the range of a couple of hertz and above. Table 27.1 provides a small selection of early works on actuators [27.25–30] suitable for micro- and nanorobotic applications (partially adapted from [27.24]).

Several extensive reviews on various actuation principles have been published [27.4, 31–34]. During the design of an actuator, the trade-offs among range of motion, force, speed (actuation frequency), power consumption, control accuracy, system reliability, robustness, load capacity, etc. must be taken into considera-

tion. This section reviews basic actuation technologies and potential applications at nanometer scales.

27.3.1 Electrostatics

Electrostatic charge arises from a build up or deficit of free electrons in a material, which can exert an attractive force on oppositely charged objects, or a repulsive force on similarly charged objects. Since electrostatic fields arise and disappear rapidly, such devices will likewise demonstrate very fast operation speeds and be little affected by ambient temperatures.

Previous investigations have produced many examples of miniature devices using electrostatic force for actuation including silicon micromotors [27.35, 36], microvalves [27.37], and microtweezers [27.38]. This type of actuation is important for achieving nanoscale actuation.

Electrostatic fields can exert great forces, but generally across very short distances. When the electric field must act over larger distances, a higher voltage will be required to maintain a given force. The extremely low current consumption associated with electrostatic devices makes for highly efficient actuation.

Table 27.1 Actuation with MEMS

Actuation principle	Type of motion	Volume (mm ³)	Speed (s ⁻¹)	Force (N)	Stroke (m)	Resolution (m)	Power density (W/m ³)	Reference
Electrostatic	Linear	400	5000	1×10^{-7}	6×10^{-6}	NA	200	[27.25]
Magnetic	Linear	$0.4 \times 0.4 \times 0.5$	1000	2.6×10^{-6}	1×10^{-4}	NA	3000	[27.26]
Piezoelectric	Linear	$25.4 \times 12.7 \times 1.6$	4000	350	1×10^{-3}	7×10^{-8}	NA	[27.27]
Actuation principle	Type of motion	Volume (mm ³)	Speed (rad/s)	Torque (Nm)	Stroke (rad)	Resolution (rad)	Power density (W/m ³)	Reference
Electrostatic	Rotational	$\pi/4 \times 0.5^2 \times 3$	40	2×10^{-7}	2π	NA	900	[27.28]
Magnetic	Rotational	$2 \times 3.7 \times 0.5$	150	1×10^{-6}	2π	$5/36\pi$	3000	[27.29]
Piezoelectric	Rotational	$\pi/4 \times 1.5^2 \times 0.5$	30	2×10^{-11}	0.7	NA	NA	[27.30]

Table 27.2 Comparison of nano actuators

Method	Efficiency	Speed	Power density
Electrostatic	Very high	Fast	Low
Electromagnetic	High	Fast	High
Piezoelectric	Very high	Fast	High
Thermomechanical	Very high	Medium	Medium
Phase change	Very high	Medium	High
Shape memory	Low	Medium	Very high
Magnetostrictive	Medium	Fast	Very high
Electrorheological	Medium	Medium	Medium
Electrohydrodynamic	Medium	Medium	Low
Diamagnetism	High	Fast	High

27.3.2 Electromagnetics

Electromagnetism arises from electric current moving through a conducting material. Attractive or repulsive forces are generated adjacent to the conductor and proportional to the current flow. Structures can be built which gather and focus electromagnetic forces, and harness these forces to create motion.

Electromagnetic fields arise and disappear rapidly, thus permitting devices with very fast operation speeds. Since electromagnetic fields can exist over a wide range of temperatures, performance is primarily limited by the properties of the materials used in constructing the actuator.

One example of a microfabricated electromagnetic actuator is a microvalve which uses a small electromagnetic coil wrapped around a silicon micromachined valve structure [27.39]. The downward scalability of electromagnetic actuators into the micro- and nano-realm may be limited by the difficulty of fabricating small electromagnetic coils. Furthermore, most electromagnetic devices require perpendicularity between the current conductor and the moving element, presenting a difficulty for planar fabrication techniques commonly used to make silicon devices.

An important advantage of electromagnetic devices is their high efficiency in converting electrical energy into mechanical work. This translates into less current consumption from the power source.

27.3.3 Piezoelectrics

Piezoelectric motion arises from the dimensional changes generated in certain crystalline materials when subjected to an electric field or to an electric charge. Structures can be built which gather and focus the force of the dimensional changes, and harness them to create motion. Typical piezoelectric materials include quartz (SiO_2), lead zirconate titanate (PZT), lithium niobate, and polymers such as polyvinylidene fluoride (PVDF).

Piezoelectric materials respond very quickly to changes in voltages and with great repeatability. They can be used to generate precise motions with repeatable oscillations, as in quartz timing crystals used in many electronic devices. Piezoelectric materials can also act as sensors, converting tension or compression strains to voltages.

On the microscale, piezoelectric materials have been used in linear inchworm drive devices and micropumps [27.40]. STMs and most nanomanipulators use piezoelectric actuators.

Piezoelectric materials operate with high force and speed, and return to a neutral position when unpowered. They exhibit very small strokes (under 1%). Alternating electric currents produce oscillations in the piezoelectric material, and operation at the sample's fundamental resonant frequency produces the largest elongation and highest power efficiency [27.41]. Piezoelectric actuators working in the *stick-slip* mode can provide millimeter to centimeter strokes. Most commercially available nanomanipulators adopt this type of actuators, such as Picomotors from New Focus and Nanomotors from Klock.

27.3.4 Other Techniques

Other techniques include thermomechanical, phase change, shape memory, magnetostrictive, electrorheological, electrohydrodynamic, diamagnetism, magnetohydrodynamic, shape changing, polymers, and biological methods (living tissues, muscle cells, etc.). Table 27.2 compares these techniques.

27.4 Imaging at the Micro- and Nanoscales

A brief overview is given of common imaging tools used in the research area of micro- and nanorobotics including optical, electron, and scanning probe microscopy. The application and integration of these tools for micro- and nanorobotics are discussed in separate sections.

In selecting a proper tool for imaging/sensing at these scales, the following factors should be first considered:

1. Specimen: size, conductivity, and environment compatibility are among the most important aspects

Table 27.3 Comparison of optical microscopes (OM) and electron microscopes

Feature	OM	TEM	SEM
General use	Surface morphology and sections (1–40 μm)	Section (40–150 nm) or small particles on thin membranes	Surface morphology
Source of illumination	Visible light	High-speed electrons	High-speed electrons
Best resolution	ca. 200 nm	ca. 0.2 nm	ca. 3–6 nm
Magnification range	10–1000 \times	500–500,000 \times	20–150,000 \times
Depth of field	0.002–0.05 nm (N.A. 1.5)	0.004–0.006 mm (N.A. 10^{-3})	0.003–1 mm
Lens type	Glass	Electromagnetic	Electromagnetic
Image ray-formation spot	On eye by lenses	On phosphorescent plate by lenses	On cathode tube by scanning device

to consider. For example, in vivo bioapplications generally require air or liquid, so lower-resolution, light microscopy should be the first choice. If higher resolution is needed, atomic force microscopy or scanning near-field optical microscopy can be used.

2. Resolution: the ability to see fine details of a specimen. Once you can resolve fine details then you can magnify them. Every microscope has a finite resolution; if you magnify objects beyond the resolution the result will be empty magnification. Roughly speaking, a light microscope cannot provide a resolution better than 200 nm. The best commercially available scanning electron microscopes (SEM) have approximately 1 nm resolution, while transmission electron microscopes (TEM) can achieve approximately 0.2 nm, and a scanning tunneling microscope (STM) working in ultrahigh vacuum under very low temperature can resolve atomic-level structures. A comparison of optical microscopy and electron microscopy is given in Table 27.3.
3. Depth of field: the range of depth that a specimen is in acceptable focus. A microscope that has a small depth of field will have to be continuously focused up and down to view a thick specimen.
4. Contrast: the ratio between dark and light. Typically, most microscopes use absorption contrast, i.e., the specimen is subjected to stains in order to be seen. This is called bright-field microscopy. There are other types of microscope that use more exotic means to generate contrast, such as phase contrast, dark field, and differential interference contrast.
5. Brightness: the amount of light. The higher a microscope magnifies the more light will be required. The illumination source should also be at a wavelength (color) that will facilitate interaction with the specimen. All microscopes fall into either of two categories based on how the specimen is illuminated. In the typical compound microscope the light passes through the specimen and is collected by the image forming optics. This is called diascopic illumination. Dissecting (stereo) microscopes

generally use episcopic illumination for use with opaque specimen. The light is reflected onto the specimen and then into the objective lens.

27.4.1 Optical Microscopy

Since their invention in the late 1500s, light microscopes have enhanced our knowledge in basic biology, biomedical research, medical diagnostics, and materials science. Light microscopes can magnify objects up to 1000 times, revealing microscopic details. Light-microscopy technology has evolved far beyond the first microscopes of Robert Hooke and Antoni van Leeuwenhoek. Special techniques and optics have been developed to reveal the structures and biochemistry of living cells. Most optical microscopes in current use are known as compound microscopes, where a magnified image of an object is produced by the objective lens, and this image is magnified by a second lens system (the ocular or eyepiece) for viewing. Microscopes have even entered the digital age, using charge-coupled devices (CCDs) and digital cameras to capture images.

The development of modern microscopy has enabled a large family of optical microscopes. For special purposes, other types of optical microscopes can be selected. These include phase-contrast microscopy, fluorescence microscopy, confocal scanning optical microscopy, and deconvolution microscopy image reconstruction.

27.4.2 Electron Microscopy

Scanning Electron Microscope (SEM)

Since the commercial availability of the SEM in 1966, it has been a valuable resource for viewing samples at a much higher resolution and depth of field than the typical optical microscope. Conventional SEMs can resolve down to the nanometer scale (≈ 1 nm) whereas an optical microscope can only resolve down to approximately 200 nm [27.42]. Unlike conventional optical microscopes, SEMs have a high depth of field which gives imaged samples a three-dimensional appearance.

Early **SEMs** were limited to viewing conductive samples. However, many of today's **SEMs** can image nonconductive samples in addition to conductive samples using variable-pressure chambers.

Transmission Electron Microscope (TEM)

The TEM can resolve to an atomic scale down to about 1 d. h. (i. e., 0.1 nm). The TEM mode of operation is similar to that of the SEM in that both microscopes contain an electron gun source of illumination. However, the TEM detects the electrons that pass through a given sample. As a result, the electron gun of the TEM operates at higher energy levels between 50–1000 kV, while the SEM's electron gun operates at around 1–30 kV. In order for proper imaging to take place, the sample must be very thin so that electrons from the beam can pass through the specimen. Electrons that do not pass through the sample cannot be detected. Unlike the SEM, the TEM produces images that are two dimensional in appearance.

27.4.3 Scanning Probe Microscopy

Scanning Tunneling Microscope (STM)

Similar to the TEM, the STM [27.19] can also resolve specimens down to the atomic scale. The scanning probe of the STM is comprised of a noble metal sharpened to an atomic-sized tip, which is mounted on a piezoelectrically driven (x, y, z) linear stage. The STM makes use of the quantum-mechanical effect known as tunneling. Electron tunneling occurs when electrons, driven by a small potential difference, flow across the gap between the probe tip and sample. This event takes place at Ångström-scale distances between the probe tip and the sample [27.43]. The tunneling current, which is typically on the order of a few nanoamperes, is directly related to the tip-sample separation distance. Thus, the tunneling current can be measured and is kept at a constant value by controlling the tip-sample gap distance (z) with a feedback control system. The probe tip is then scanned (x, y) along the entire surface of the sample. Since the control system maintains a constant tunneling current, and thus maintains a constant tip-sample distance (z), the result of a scan yields a $z(x, y)$ terrain map of the sample with enough resolution to de-

tect atomic-scale features. The STM can achieve faster imaging by operating in so-called constant-height mode in which the probe tip is scanned in a plane parallel to the average surface portion. The tip-sample distance (z) can then be inferred directly from the measured tunneling current [27.43].

Atomic Force Microscope (AFM)

The AFM [27.44] is considered to be a spin-off of the STM. One shortcoming of the STM is that it requires conductive probe tips and samples to work properly. The AFM was developed in order to view nonconductive samples, giving it a wider applicability than the STM. In addition to imaging nonconductive samples, the AFM can also image samples immersed in liquid, which is useful for biological applications [27.45]. Although the STM and AFM are similar in that they both scan the surface of a sample with an atomically sharp probe, they operate under slightly different principles. The AFM is based on interatomic forces as opposed to the electron tunneling used in the STM. The AFM probe tip is mounted on the end of a microscale cantilever beam. At very short separations, the forces between atoms in the probe tip and atoms in the sample cause the cantilever to deflect. This deflection is usually measured by striking the back of the cantilever with a laser. The reflection of the laser beam hits a photodetector, which can be used to recover the deflection of the cantilever. The force can then be calculated by using Hooke's law, which simply relates the applied force to the stiffness and deflection of a material. The forces that are measured can be on the scale of piconewtons [27.43]. The AFM has three main modes of operation known as contact mode, noncontact mode, and tapping mode.

Unlike the SEM and TEM, both the STM and AFM do not require a vacuum environment in order to function. However, a high vacuum is advantageous in order to keep the samples from becoming contaminated from the surrounding environment as well as controlling humidity. In addition, atomic resolution in air is hardly possible with an AFM due to humidity. As a result of humidity, a water film is formed and creates problems because of capillary forces. This can be resolved by operating in vacuum environment or completely in a liquid solution [27.43].

27.5 Fabrication

The design of micro- and nanorobotic devices is inextricably linked to available fabrication techniques. However, though the development of microfabrication processes has become somewhat stable over the past

decade, nanofabrication processes are still being actively pursued, and the design constraints generated by these processes are relatively unexplored. This section will briefly highlight the processes used in conventional

microfabrication including lithography, thin-film deposition, chemical etching, and electrodeposition, and describe some emerging techniques for nanofabrication.

Most micro- and nanofabrication techniques have their roots in the standard fabrication methods developed for the semiconductor industry [27.46–48]. Therefore, a clear understanding of these techniques is necessary for anyone embarking on a research and development path in the micro/nano area.

27.5.1 Microfabrication

In this section, we will discuss the major microfabrication techniques used most frequently in the manufacturing of microstructures.

Photolithography

Lithography is the technique used to transfer a computer-generated pattern onto a substrate (silicon, glass, GaAs, etc.). This pattern is subsequently used to etch an underlying thin film (oxide, nitride, etc.) for various purposes (doping, etching, etc.). Although photolithography, i.e., lithography using an ultraviolet (UV) light source, is by far the most widely used lithography technique in microelectronic fabrication, electron-beam (e-beam) and X-ray lithography are two alternatives that have attracted considerable attention in the MEMS and nanofabrication areas. We will discuss photolithography in this section and postpone the discussion of e-beam and X-ray techniques to the subsequent sections dealing with nanofabrication.

The starting point following the creation of the computer layout for a specific fabrication sequence is the generation of a photomask. This involves a sequence of photographic processes (using optical or e-beam pattern generators) that results in a glass plate having the desired pattern in the form of a thin (≈ 100 nm) chromium layer. Following the generation of photomask, the lithography and etching process can proceed as shown in Fig. 27.2. After depositing the desired material on the substrate, the photolithography process starts with spin-coating the substrate with a photoresist. This is a polymeric photosensitive material that can be spun onto the wafer in liquid form; usually an adhesion promoter such as hexamethyldisilazane (HMDS) is used prior to the application of the resist. The spinning speed and photoresist viscosity will determine the final resist thickness, which is typically 0.5 – 2.5 μm . Two different kinds of photoresist are available: positive and negative. With a positive resist, the UV-exposed areas will be dissolved in the subsequent development stage, whereas with a negative photoresist, the exposed areas will remain intact

after the development. After spinning the photoresist on the wafer, the substrate is soft-baked (5 – 30 min at 60 – 100 $^{\circ}\text{C}$ in order to remove the solvents from the resist and improve the adhesion. Subsequently, the mask is aligned to the wafer and the photoresist is exposed to a UV source.

After exposure, the photoresist is developed in a process similar to the development of photographic film. The resist is subsequently hard-baked (20 – 30 min at 120 – 180 $^{\circ}\text{C}$ in order to further improve the adhesion. The hard-bake step concludes the photolithography sequence by creating the desired pattern on the wafer. Next, the underlying thin film is etched, and the photoresist is stripped in acetone or other organic solvent. Figure 27.3 shows a schematic of the photolithography steps with a positive photoresist.

Thin-Film Deposition and Doping

Thin-film deposition and doping are used extensively in micro- and nanofabrication technologies. Most of the fabricated structures contain materials other than that of the substrate, which are obtained by various deposition techniques, or by modification of the substrate. These techniques include oxidation, doping, chemical vapor deposition (CVD), physical vapor deposition (PVD), and electroplating.

Etching and Substrate Removal

For micro- and nanofabrication, in addition to thin film etching, often the substrate (silicon, glass, GaAs, etc.) needs to be removed in order to create various mechanical structures (beams, plates, etc.). Two important figures of merit for any etching process are selectivity and directionality.

Selectivity is the degree to which the etchant can differentiate between the masking layer and the layer to

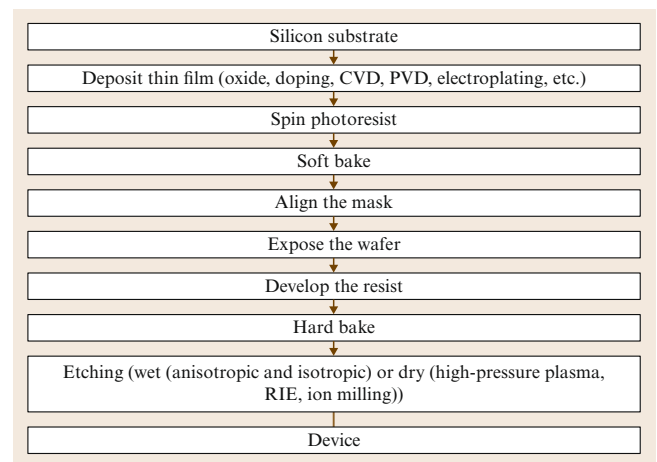

Fig. 27.2 Typical microfabrication process flow

be etched. Directionality has to do with the etch profile under the mask. In an isotropic etch, the etchant attacks the material in all directions at the same rate, creating a semicircular profile under the mask (Fig. 27.4a). In an anisotropic etch, the dissolution rate depends on specific directions, and one can obtain straight sidewalls or other noncircular profiles (Fig. 27.4b). One can also divide the various etching techniques into wet and dry categories. Due to the lateral undercut, the minimum feature size achievable with wet etchants is limited to $> 3 \mu\text{m}$. Photoresist and silicon nitride are the two most common masking materials for the wet oxide etch. Anisotropic and isotropic wet etching of crystalline (silicon and gallium arsenide) and noncrystalline (glass) substrates are important topics in micro- and nanofabrication [27.49–53].

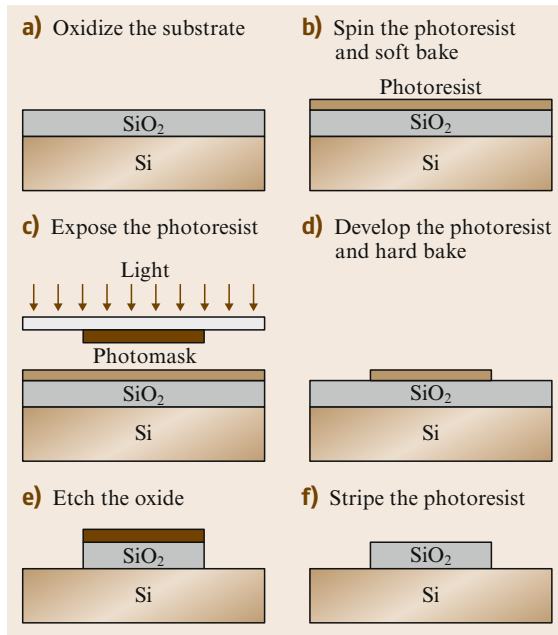

Fig. 27.3a–f Schematic drawing of the photolithographic steps with a positive photoresist (PR) (a) Oxidize the substrate (b) spin the photoresist and soft bake (c) expose the photoresist (d) develop the photoresist and hard bake (e) etch the oxide (f) stripe the photoresist

Fig. 27.4a,b Profile for isotropic (a) and anisotropic (b) etch through a photoresist mask

The anisotropic behavior of these etchants with respect to the (111) planes have been used extensively to create beams, membranes, and other mechanical and structural components. Figure 27.5 shows the typical cross sections of (100) silicon wafers etched with an anisotropic wet etchant. As can be seen, the (111) slow planes are exposed and creating 54.7° sloped sidewalls. Depending on the dimensions of the mask opening, a V-groove or a trapezoidal trench is formed in the (100) wafer. A large enough opening will allow the silicon to be etched all the way through the wafer, thus creating a thin dielectric membrane of the other side. It should be mentioned that exposed convex corners have a higher etch rate than the concave ones, resulting in an undercut that can be used to create dielectric (e.g., nitride) cantilever beams.

Dry etching techniques are largely plasma based. They have several advantages compared with wet etching. These include smaller undercut (allowing smaller lines to be patterned) and higher anisotropy (allowing high-aspect-ratio vertical structures). However, the selectivity of dry etching techniques is lower than the wet etchants, and one must take into account the finite etch rate of the masking materials. The three basic dry etching techniques, namely high-pressure plasma etching, reactive-ion etching (RIE), and ion milling, utilize different mechanisms to obtain directionality.

27.5.2 Nanofabrication

The design and fabrication of NEMS is an emerging area being pursued by an increasing number of researchers. Two approaches to nanofabrication, top-down and bottom-up, have been identified by the nanotechnology research community and are being independently investigated by various researchers. Top-down approaches are based on microfabrication and include technologies such as nanolithography, nanoimprinting, and chemical etching. Presently, these are 2-D fabrication processes with relatively low resolution. Bottom-up strategies are assembly-based techniques. Currently these strategies include techniques such as self-assembly, dip-pen lithography, and directed self-assembly. These techniques can generate regular nanopatterns at large scales.

Fig. 27.5 Anisotropic etch profiles for (100) silicon wafers

In this section, we will discuss three major nanofabrication techniques. These include:

1. **e-beam** and *nanoimprint* fabrication
2. *Epitaxy* and *strain engineering*, and
3. Dip-pen nanolithography.

E-beam Lithography and Nanoimprint Fabrication

In previous sections, we discussed several important lithography techniques commonly used in **MEMS** and microfabrication. These include various forms of **UV** (regular, deep, and extreme) and X-ray lithography. However, due to the lack of resolution (in the case of the **UV**), or the difficulty in manufacturing mask and radiation sources (X-ray), these techniques are not suitable for nanometer-scale fabrication. E-beam lithography is an attractive alternative technique for fabricating nanostructures [27.53]. It uses an electron beam to expose an electron-sensitive resist such as polymethyl methacrylate (**PMMA**) dissolved in trichlorobenzene (positive) or polychloromethylstyrene (negative).

The **e-beam** gun is usually part of an **SEM**, although a **TEM** can also be used. Although electron wavelengths on the order of 1 Å can easily be achieved, electron scattering in the resist limits the attainable resolutions to > 10 nm. The beam control and pattern generation are achieved through a computer interface.

E-beam lithography is serial and hence has a low throughput. Although this is not a major concern in fabricating devices used in studying fundamental microphysics, it severely limits large-scale nanofabrication. E-beam lithography, in conjunction with such processes

as lift-off, etching, and electrodeposition, can be used to fabricate various nanostructures.

An interesting new technique that circumvents the serial and low-throughput limitations of the **e-beam** lithography for fabricating nanostructures is nanoimprint technology [27.54]. This technique uses an **e-beam**-fabricated hard material master (or mold) to stamp and deform a polymeric resist. This is usually followed by a reactive-ion etching step to transfer the stamped pattern to the substrate. This technique is economically superior, since a single stamp can be used repeatedly to fabricate a large number of nanostructures.

Epitaxy and Strain Engineering

Atomic-precision deposition techniques such as molecular-beam epitaxy (**MBE**) and metallo-organic chemical vapor deposition (**MOCVD**) have proven to be effective tools in fabricating a variety of quantum confinement structures and devices (quantum well lasers, photodetectors, resonant tunneling diodes, etc.) [27.55–57].

Dip-Pen Nanolithography

In dip-pen nanolithography (**DPN**), the tip of an **AFM** operated in air is *inked* with a chemical of interest and brought into contact with a surface. The ink molecules flow from the tip onto the surface as with a fountain pen. Line widths down to 12 nm with spatial resolution of 5 nm have been demonstrated with this technique [27.58]. Species patterned with **DPN** include conducting polymers, gold, dendrimers, deoxyribonucleic acid (**DNA**), organic dyes, antibodies, and alkanethiols.

27.6 Microassembly

Assembly is often required in macroscale product manufacturing in order to reduce the complexity and cost of the manufacturing process. Assembly makes it possible to build complex products from relatively simple parts and to integrate incompatible manufacturing processes. It also makes maintenance and replacement possible. The extension of assembly techniques into the microscale is driven by the development of modern design and manufacturing technologies in the pursuit of miniaturization and function integration, especially by the development of integrated circuit (**IC**) [27.59] and **MEMS** fabrication techniques. With the extension of manufacturing technology into the microscale and even nanoscale domain, the term microassembly has been created to refer specifically to assembly operations per-

formed at the micro/mesoscale [27.60]. To give a formal definition, microassembly is the assembly of objects with microscale and/or mesoscale features under microscale tolerances [27.61].

27.6.1 Automated Microassembly Systems

Microassembly plays the role of an enabling technology in various processes of **MEMS** fabrication, including device fabrication, packaging, and interconnection. **MEMS** device fabrication is fundamentally different from the highly modular **IC** fabrication in that it often requires the machining of complex-shaped three-dimensional (**3-D**) mechanical structures [27.51]. However, almost all current **MEMS** fabrication tech-

niques are subject to constraints in limited allowable materials, limited capabilities in true 3-D fabrication, and the requirement of fabrication process compatibility. Microassembly provides a possible solution to these constraints. For example, incompatible fabrication processes can be integrated through assembly. This makes it possible to use *nontraditional* fabrication techniques that are not necessarily based on semiconductor materials, such as laser cutting, microwire electrical discharge machining (EDM), and micromilling [27.62]. Complex 3-D structures can also be developed using parts with relatively simple geometry [27.63, 64]. Microassembly is also crucial to MEMS packaging and interconnection [27.65, 66].

From the perspective of robotic systems and automation, MEMS device fabrication and packaging share many common assembly requirements. A fundamental commonality of both processes is the requirement of the ability to manipulate micro/mesoscale objects so that precise (i. e., microscale tolerance) spatial relations can be established (e.g., die alignment, part insertion) and certain physical/chemical processes (e.g., die bonding, surface coating) can be performed. Another common requirement is to control the interaction force involved. MEMS devices often have fragile structures such as thin beams or membranes. This requires controlling the interactive force in manipulation operations. Typically, the force magnitude resides in the range from millinewtons to micronewtons.

MEMS devices are often three-dimensional. MEMS packaging requires both electrical interconnection for signal transmission and mechanical interconnection for the interaction of the packaged device with its external environment [27.51, 67]. Many such mechanical interconnections require three-dimensional manipulation and three-dimensional force control. The actual operations are highly application specific, which pose great challenges to the development of automated microassembly systems. Automated IC packaging systems can be used for the packaging of certain MEMS devices such as accelerometers and gyros. However, packaging of microfluidic devices, optical MEMS devices, and hybrid microsystems often require the development of new automated microassembly techniques and systems.

The selection of assembly mode is among the first decisions to be made in developing automated microassembly systems. Sequential microassembly requires the use of micromanipulators and sensory feedback. At each moment, only one or a few parts are being assembled. Depending on the physical effects used, parallel microassembly can be either deterministic or stochastic [27.68]. Die bonding is an example of deterministic parallel microassembly. In stochastic parallel

microassembly, large numbers of parts are assembled simultaneously using distributed physical effects such as electrostatic force, capillary force, centrifugal force, or vibration [27.60, 69–71]. In fact, the basic philosophy of stochastic parallel microassembly is to minimize the use of sensory feedback.

Each of these assembly modes has both advantages and disadvantages. Each has its own suitable applications. Deterministic parallel assembly shares several commonalities with sequential microassembly. For example, sensory feedback is often used in deterministic parallel microassembly. However, deterministic parallel microassembly requires high relative positioning accuracy between parts. In addition, only simple planar structure features can be assembled in order to make parallel operation possible.

Due to the requirement of MEMS packaging for three-dimensional manipulation and microassembly, it can be expected that automated sequential microassembly will be the most widely adopted solution. In particular, those MEMS packaging applications that require the control of multiple-degree-of-freedom (DOF) interaction force should use sequential microassembly. The major possible disadvantage of sequential microassembly is its low throughput. This constraint can often be overcome by appropriate system design.

Here we introduce a three-dimensional microassembly example that originates from an industrial application [27.61]. It is significantly different from wire bonding and die bonding applications in that high-precision 3-D part insertion is required. Together with other examples, it will be used throughout this section to illustrate the major concepts and techniques and the logic connections between each functional unit of an automated microassembly system.

The assembly task is to pick up micromachined thin metal parts that are transferred to the assembly workcell on a vacuum-release tray (Fig. 27.6a–c), and insert them into vertically deep reactive ion etching (DRIE) etched holes in a silicon wafer (Fig. 27.6d). The wafers can have diameters up to 8 inches. The holes on each wafer form regular arrays consisting of approximately 50 holes each. However, these arrays may not be regularly distributed on the wafer. Typically, hundreds of parts are to be assembled on each wafer. In general, each assembly operation is a typical rectangular-peg-into-a-rectangular-hole problem. Each metal part is approximately half a millimeter in width and less than 100 μm in thickness at its rectangular tip. The total assembly tolerance is typically smaller than 10 μm in the vertical direction, and smaller than 20 μm in the horizontal direction. This task is a typical application of 3-D microassembly techniques.

27.6.2 Microassembly System Design

This section discusses the design of automated microassembly systems from the perspective of robotic systems and automation. Performance objects to be achieved include high reliability, high throughput, high flexibility, and low cost.

General Guidelines

Taking a System Perspective. An automated microassembly system consists of many functional units and must integrate techniques from a diverse range of areas such as robotics, computer vision, microscope optics, physics, and chemistry. It is therefore important to consider the interaction between these units.

Emphasizing the Coupling with Packaging Processes. Although in this section microassembly techniques are addressed primarily from the perspective of robotics for the clarity of presentation, robotic system designers must recognize the strong dependence of architecture design of the robotic systems on the packaging process being implemented. This connection should be emphasized from the beginning of system development.

Design for Reconfigurability. Automated packaging machines must be designed so that they can be customized for a wide variety of applications. Reconfigurability is therefore a basic design requirement. Typically, modular design based on function decomposition is desirable. Support for tool replacement is essential.

The design of automated microassembly systems is strongly dependent on the assembly tolerance required. First of all, the repeatability of the motion control system and the micromanipulator used is determined by the required assembly tolerance. In addition, assembly tolerance often determines the minimum resolution of the microscope optics. General microassembly tasks may only require microscopic vision feedback and manipulators with microscale repeatability, while complex microassembly tasks may also require the in-

tegration of microforce and vision feedback [27.72, 73].

Automated microassembly systems must be able to support a wide variety of material-handling tools, which include part transfer tools, bulk feeders, wafer-handling tools, magazine loaders and unloaders, etc.

The role of the micromanipulator is to provide multiple-DOF fine motion control. The role of the microgripper is to grasp objects in pick-and-place and other assembly operations. Their efficiency and robustness will to a great extent decide the performance of the entire system. Microgripper design is also closely related to the design of fixtures for microassembly operations.

Major environment factors include clean-room requirements, temperature, humidity, airflow, etc. Certain assembly operations must be performed in a clean room. This requires that the design of automated microassembly systems comply with relevant standards. Some packaging processes such as eutectic bonding must be performed under high temperature. Consequently, the potential influence of high temperature on motion control system and microscope optics must be considered. For the manipulation of microscale objects, environment conditions such as temperature and humidity can have a major influence on adhesion forces [27.74, 75]. Therefore, it is often important to consider environment control in system design.

Assembly Process Flow: An Example

The micromachined metal parts (Fig. 27.6c) are horizontally transferred to the workcell on the vacuum-release tray (Fig. 27.6b). The wafer is placed on a wafer mount perpendicular to the horizontal plane (Fig. 27.6b). This configuration does not require the flipping of the thin metal parts and is advantageous in terms of reliability and efficiency. There are two major operations in each assembly cycle: pickup and insertion. Under the configuration shown in Fig. 27.7a, all the operations are performed by the same workcell. Complex packaging operations must often be decomposed and performed by multiple workcells [27.76].

General System Architecture

An automated microassembly system typically consists of the following functional units.

Large Workspace Positioning Unit. A large workspace and long-range positioning motion are required in most microassembly operations. The large workspace is necessary to accommodate different functional units, part feeders, and various tools.

In general, off-the-shelf motion control systems developed for automated IC packaging equipment can be adopted directly. For the task described in Sect. 27.6.1, the DRIE-etched holes are distributed on wafers up to 8 inches in diameter. This requires the assembly system to have a commensurate working space and high positioning speed. The coarse positioning unit has four DOFs (Fig. 27.7a). Planar motion in the horizontal direction is provided by an open-frame high-precision XY table with a travel of 32 cm (12 inch) and a repeatability of 1 μm in both directions. Position feedback with a resolution of 0.1 μm is provided by two linear encoders. A dual-loop PID (proportional–integral–derivative) plus feedforward control scheme is used for each axis. The internal speed loop is closed on the rotary encoder on the motor. The external position loop is closed on the linear encoder. Each wafer is placed on the vertical wafer mount that provides both linear and rotational control (Fig. 27.7b). Vertical motions of the wafer mount are provided by a linear slide with a travel of 20 cm (8 inch) and a repeatability of 5 μm . It is also controlled using a PID plus feedforward algorithm. Both the XY table and the vertical linear slides are actuated using alternating-current (AC) servo motors. The rotation of the wafer mount is actuated by an Oriental PK545AUA microstep motor with a maximum resolution of 0.0028° step. All low-level controllers are commanded and coordinated by a host computer [27.61].

For applications requiring repeatability of one micron or greater, it is convenient to use conventional posi-

tioning tables to implement coarse range motions. These tables typically use leadscrew or ballscrew drives and ball or roller bearings. For applications requiring sub-micron or nanometer repeatability, a few solutions are also commercially available. For example, piezoactuators are often used for nanometer repeatability motion. The disadvantage of piezoactuators is that their travel range is small, typically on the order of 100 microns. As another example, a series of positioning stages with submicron repeatability based on direct-drive linear actuators and air bearings is available from Aerotech. It is also possible to use parallel structure mechanisms such as a Stewart platform [27.77]. In general, the development of IC manufacturing towards the deep submicron level provides a major driving force behind the development of these motion control techniques.

Micromanipulator Unit. Fine pose (position and orientation) control is required in operations such as 3-D precision alignment and assembly. For example, the six DOFs required by the task introduced in Sect. 27.6.1 are implemented on separate structures. The three Cartesian DOF are provided by an adapted Sutter MP285 micromanipulator, which also provides yaw motions with its rotational DOF (Fig. 27.7c). Roll motions are implemented on the wafer mount (Fig. 27.7b). The pitch movement of the metal part after pickup is not motorized and is implemented through manual adjustment and calibration before assembly. More discussion of micromanipulator configuration can be found in [27.61].

Two principles need to be considered in implementing motion control for automated 3-D microassembly. The first is the partition of large-workspace coarse positioning unit and the fine positioning micromanipulator unit. The second is the decomposition and distributed implementation of multiple DOFs. In practice, the actual implementations of these principles are highly application specific. For certain applications, if a large-range positioning unit is sufficient to satisfy assembly

Fig. 27.7a–c An experimental microassembly workcell (a) System overview (b) assembly scene (c) micromanipulator unit

tolerance requirements, the separate implementation of a micromanipulator may even be unnecessary.

In general, the separation of a micromanipulator unit will facilitate the implementation of high-bandwidth motion control. However, this separation normally brings redundancy to the entire motion control system. The functioning of the high-precision micromanipulator must also rely on closed-loop feedback control, especially microscopic vision feedback.

Automated Microgripper Unit. The function of a microgripper is to provide geometrical and physical constraints (grasping) in pick-and-place and assembly operations. The reliability and efficiency of the microgripper is critical to the performance of the entire automated microassembly system. Several factors must be considered in micromanipulator design. First of all, as the micromanipulator end-effector, the microgripper must be constantly monitored under a microscope. Therefore, it must be small in size and suitable in shape to remain in the microscope's field of view and to minimize occlusion. Secondly, it is important to consider the different governing physics and to explore the use of various gripping forces [27.77]. Thirdly, microgrippers are used in both part pick-and-place and assembly. Since assembly operations typically require more constraints, microgrippers designed for pick-and-place operations may not necessarily be suitable for assembly operations. In fact, the microassembly task described in Sect. 27.6.2 is performed using a combined microgripper [27.61]. Microgripper development is often closely related to the development of fixtures that can also have microscale sizes.

Microscope Optics and Imaging Unit. The function of the microscope optics and imaging unit is to provide noncontact measurement of the geometry, motion, and spatial relations of assembly objects. Typical configurations of commercial device bonding systems use one or two vertical microscopes. An inverted microscope configuration is commonly used for backside alignment. On the other hand, 3-D microassembly may require two camera views in a stereo configuration. In the system shown in Fig. 27.7a, a total of four different views can be provided to its human operator: a global view of the entire assembly scene, a vertical microscopic view for part pickup, and two lateral microscopic views for the fine position and orientation adjustments during the final microassembly operations. Each view uses a CCD camera with a matching optical system. All images are captured using a Matrox Corona peripheral component interconnect (PCI) frame grabber.

Microscopic visual feedback is crucial for precise 3-D alignment. Provided that resolution requirements

of the assembly task can be satisfied, microscope optics with larger working distances is desirable. For the assembly task addressed in Sect. 27.6.1, an Edmund Scientific VZM 450i zoom microscope with a $1\times$ objective is used to provide the right view. Its working distance is approximately 90 mm, with a resolution of $7.5\text{ }\mu\text{m}$. The vertical view is also provided by a VZM 450i microscope with a $0.5\times$ objective to guide pickup operations. Its field of view can range from $2.8\times 2.8\text{ mm}$ to $17.6\times 17.6\text{ mm}$. Its working distance is approximately 147 mm.

If visual servoing is required in automate assembly operations, a stereo configuration formed by adding another lateral view may be necessary. Higher resolution may be necessary in some microassembly tasks. In such cases, the same configuration can be used with higher-resolution microscope optics, for example, two Navitar TenX zoom microscopes with Mitutoyo ultralong-working-distance M Plan Apo $10\times$ objectives have been used in this configuration by the authors. The resolution of each microscope is $1\text{ }\mu\text{m}$, with a working distance of 33.5 mm. Consequently, the usable workspace of the micromanipulator is reduced [27.61].

The global view is implemented using a miniature Marshall V-1260 board camera to monitor the status of the entire assembly scene. It plays an important role in helping the operator to understand gross spatial relations and preventing operation errors.

From the perspective of robotic systems, the development of automation microassembly systems for complex 3-D microassembly operation will rely on the development of:

1. Compact, robust and high-speed micromanipulators with 5–6 DOFs.
2. Highly reliable and efficient microgrippers that are suitable for working under microscopes. Such grippers should have active force control or passive compliance to avoid damage to MEMS devices.
3. Three-dimensional microscopic computer vision techniques, three-dimensional microforce measurement and control techniques, and their integration.

27.6.3 Basic Microassembly Techniques

This section introduces a few supporting techniques important to automated microassembly systems, including machine vision techniques, microforce control techniques, and simulation verification of assembly strategy.

Machine Vision Techniques

Machine vision techniques are widely used in the semiconductor industry. The major difference between ma-

chine vision and general computer vision [27.78] is that, unlike natural objects and scenes, industrial objects and scenes can often be artificially designed and configured. This advantage often makes it possible to significantly reduce the complexity and enhance the robustness of vision techniques. The applications of machine vision techniques can generally be categorized into the following two classes based on the requirement of real-time processing.

Non-Time-Critical Vision Applications. These applications do not require visual feedback for high-bandwidth real-time control. Examples include object recognition and packaging quality inspection [27.79].

Time-Critical Vision Applications. These applications require real-time visual feedback. Examples include vision-guided pick-and-place, alignment, insertion, etc. [27.80]. An introduction to 3-D computer vision techniques can be found in [27.81]. A standard introduction to visual servoing techniques can be found in [27.82].

Several commercial software packages are available from suppliers such as Cognex, Coreco Imaging, and National Instruments.

Microforce Control Techniques

The theory of force control has been studied by the robotics community for more than 50 years [27.83, 84]. Several theoretical frameworks and many control algorithms have been proposed and experimentally verified. A variety of macroscale multiple-DOF force sensors have been developed.

Force control is also crucial to microassembly. For example, contact forces in device bonding must often be programmed and precisely controlled. In general, many of the macroscale force control techniques can be applied at micro/mesoscales. Force control for device bonding is essentially 1-D and involves force on the order of several newtons. On the other hand, in the manipulation of micro/mesoscale parts, the magnitude of interactive force typically ranges from millinewtons (10^{-3} N) to micronewtons (10^{-6} N). Forces of this magnitude are often referred to as *microforces*. A major technical challenge in implementing microforce control is the lack of multiple-DOF microforce sensors. A basic requirement for multiple-DOF microforce sensors is that they must be miniature in size. The manufacturing of these sensors normally requires the use of micro-machining, including MEMS techniques. There are two major microforce sensing configurations.

Stand-Alone Force Sensor. The advantage of this configuration is that the sensor is general purpose

and can be used with different microgrippers. Most macroscale multiple-DOF force sensors are of this type. However, this also requires the sensor to have sufficient structural stiffness to support the static load of microgripper, which is often significantly larger than the force resolution to be reached.

Embedded Force Sensor. Micro strain gages can be attached to microgrippers [27.85]. Force-sensitive materials can also be deposited on microgrippers. This configuration avoids the issue of static load. However, such force sensing capabilities are dependent on the microgripper design, which often is not necessarily optimal for the measurement of multiple-DOF microforce/torque.

Complex and high-precision microassembly tasks also require the integration of microscopic machine vision with microforce control. Simple integration techniques use a gating/switching scheme [27.72, 86]. For more integrated approaches, visual impedance can be used [27.73].

Simulation Verification of Assembly Strategies

In many microassembly tasks, the distances between adjacent features are often on the meso/microscale. Therefore, selecting the correct assembly sequence is important for collision avoidance. In addition, due to the limited working distance of microscopes, microassembly operations must often be performed in a limited space using micromanipulators. Collision avoidance is critical to avoiding equipment or device damage. Potential collisions can be found and avoided by using offline simulation software. Many commercially available offline robot programming tools can provide this function.

Microassembly Tool

The end-effector of a micromanipulator in an automated microassembly system is often in the form of a microgripper, whose reliability and efficiency greatly influence the reliability and efficiency of the entire system. The microgripper must often be as small as possible. Its design must also minimize potential damage to fragile MEMS parts. This often requires passive compliance in structural design.

Microgrippers with integrated MEMS actuators can be fabricated monolithically and thus can be more compact in size. Several physical effects are commonly used in MEMS actuators, including electrostatic force and piezoelectric force [27.87], shape memory alloy (SMA) [27.88, 89], and thermal deformation [27.63, 90]. Currently, the major limitation is that it is difficult for MEMS actuators to generate sufficient travel, force, and power output. Alternatively, another solution

is to provide actuation externally [27.61, 91]. The advantage is that sufficient travel and force and power output can be more easily obtained. The major dis-

advantage is that the microgripper is less compact in size. This could become a major obstacle to its applications.

27.7 Microrobotics

Today, more and more microrobotic devices are enabling new applications in various fields. Besides microassembly, microrobotics can play important roles in other industry fields for manipulation, characterization, inspection, and maintenance, and in biotechnology for, e.g., manipulating cells, a field referred to as biomicrorobotics.

27.7.1 Introduction

Microrobotics is a field that combines the established theory and techniques of robotics with the exciting new tools provided by MEMS technology in order to create intelligent machines that operate at micron scales. As stated by authors reviewing the microrobotics field [27.31, 92], many *micro* terms such as *micromechatronics*, *micromechanism*, *micromachines*, and *microrobots* are used synonymously to indicate a wide range of devices whose function is related to a *small* scale; however, *small* scale is a relative term so a clearer definition is needed.

The obvious difference between a macrorobot and a microrobot is the size of the robot. Thus, one definition of a microrobot is *a device having dimensions smaller than classical watch-making parts (i. e., μm to mm) and having the ability to move, apply forces and manipulate objects in a workspace with dimensions in the micrometer or submicrometer range* [27.93]. However, in many cases it is important that the robot can move over much larger distances. This task-specific definition is quite wide and includes several types of very small robots as well as stationary micromanipulation systems, which are a few decimeters in size but can carry out very precise manipulation (in the micron or even nanometer range) [27.92].

Besides classification by task or size, microrobots can also be classified by their mobility and functionality [27.31, 94]. Many robots usually consist of sensors and actuators, a control unit, and an energy source.

Depending on the arrangement of these components, one can classify microrobots according to the following criteria: locomotive and positioning possibility (yes or no), manipulation possibility (yes or no), control type (wireless or tethered), and autonomy. Figure 27.8 illustrates 15 different possible microrobot configurations by combining the four criteria [27.31, 94].

As depicted in Fig. 27.8 (taken from [27.24]), the classification is dependent on the following microrobot components: the control unit (CU), the power source (PS), the actuators necessary for moving the robot platform (i. e., the robot drive for locomotion and positioning; AP), and the actuators necessary for operation (i. e., manipulation using robot arms and hands; AM). Besides the different actuation functions, sensory functions are also needed, for example, tactile sensors for microgrippers or charge-coupled device (CCD) cameras for endoscopic applications (compare Fig. 27.8d and a).

The ultimate goal is to create a fully autonomous, wireless mobile microrobot equipped with suitable microtools according to Fig. 27.8o. Because this is a very difficult task, a good start is to investigate the possibility of making silicon microrobot platforms that are steered and powered through wires, like the one in Fig. 27.8c, and to study their locomotion capability.

The majority of MEMS-based microrobotic devices developed so far could be categorized as moveable links – microcatheters [27.95, 96], according to Fig. 27.8a, or microgrippers [27.25], such as those in Fig. 27.8d, or the microgrippers [27.97, 98] shown in Fig. 27.8e. Among the research publications covering locomotive microrobots, most publications have addressed microconveyance systems (Fig. 27.8b) [27.99–102]. Robots using external sources for locomotion could be used (compare Fig. 27.8b,f,j,n). According to Fatikow and Rembold [27.92], several researchers are working on methods to navigate micromechanisms through human blood vessels; however, these microrobots are difficult to control. Examples of partially autonomous systems (compare Fig. 27.8j) are the concept for so-called *smart pills*. Centimeter-sized pills for sensing temperature and/or pH inside the body have been presented [27.103, 104] as well as pills equipped with video cameras [27.105]. The pill is swallowed and transported to the part of the body where one wants to measure or record a video sequence. The information of the measured parameter or the signals from the camera is then transmitted (telemetrically) out of the body. More sophisticated approaches involving actuators for drug delivery of various kinds have also been proposed [27.92, 104]. The position of the pill inside the body is located by an X-ray monitor or ultrasound.

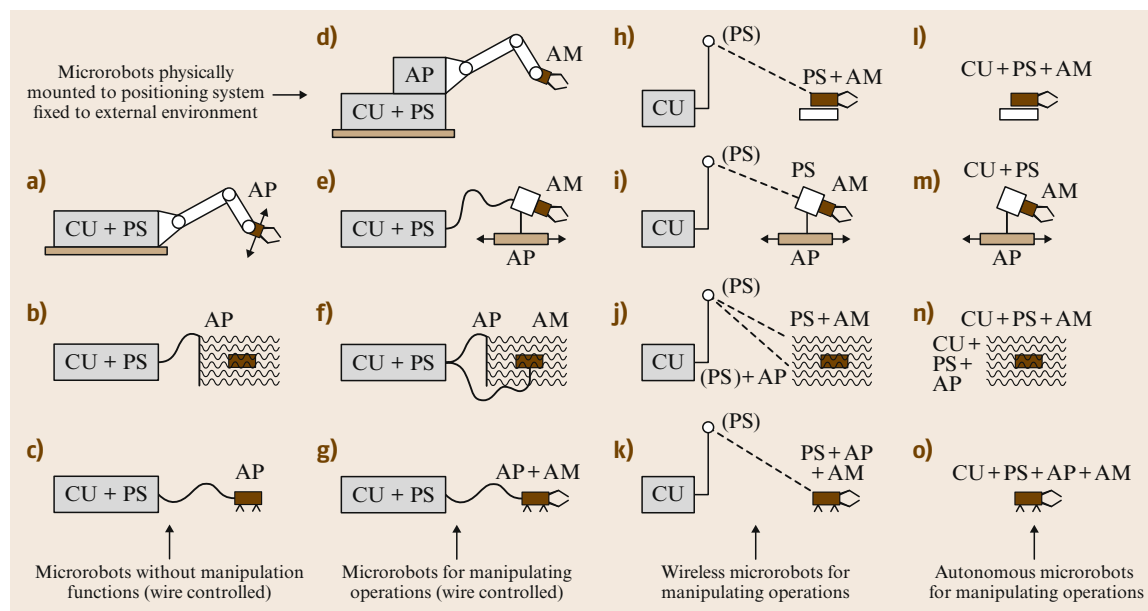

Fig. 27.8a–o Classification of microrobots by functionality (modification of earlier presented classification schemes [27.12, 31, 92, 93]). (CU indicates the control unit; PS, the power source or power supply; AP, the actuators for positioning; AM, the actuators for manipulation): (a–c) Microrobots without manipulation functions (wire controlled), (d–g) microrobots for manipulating operations (wire controlled), (h–k) wireless microrobots for manipulating operations, (l–o) autonomous microrobots for manipulating operations, (d, h, l) microrobots physically mounted to positioning system fixed to external environment

As soon as the pill reaches an infected area, a drug encapsulated in the pill can be released by the actuators onboard. External communication could be realized through radio signals.

Several important results have been presented regarding walking microrobots (Fig. 27.8c,g,k) fabricated by MEMS technologies and batch manufacturing. Different approaches for surface-micromachined robots [27.106, 107] and for a piezoelectric dry-reactive-ion-etched microrobot should be mentioned. A suitable low-power application-specific integrated circuit (ASIC) for robot control has been successfully tested and is planned to be integrated on a walking microrobot [27.108]. The large European Esprit project MINIMAN (1997) has the goal of developing moveable microrobotic platforms with integrated tools with six degrees of freedom for applications such as microassembly within an SEM and involves different MEMS research groups from several universities and companies across Europe. Further, miniature robot systems with MEMS/MST (microsystem technology) components have been developed [27.109].

Several research publications on gnat minirobots and actuator technologies for MEMS microrobots [27.3, 110] were reported by US researchers in the early 1990s, and several groups in Japan are

also currently developing miniaturized robots based on MEMS devices [27.8]. In Japan, an extensive ten-year program on *micromachine technology*, supported by the Ministry of International Trade and Industry (MITI), started in 1991. One of the goals of this project is to create micro-sized and miniature robots for microfactory, medical technology, and maintenance applications. Several microrobotic devices, including locomotive robots and microconveyers, have been produced within this program. Miniature robot devices or vehicles [27.111] for locomotive tasks, containing several MEMS components, have been presented. Even though great efforts have been made on robot miniaturization using MEMS technologies, no experimental results on MEMS batch-fabricated microrobots suitable for autonomous walking (i. e., robust enough to be able to carry its own power source or to be powered by telemetric means) have been presented yet. The first batch-fabricated MEMS-based microrobot platform able to walk was presented in 1999 [27.112]. However, this robot was powered through wires and was not equipped with manipulation actuators. Besides walking microrobotic devices, several reports on flying [27.113–115] and swimming [27.116] robots have been published. Micromotors and gear boxes made using LIGA technology (a high-precision, lithograph-

ically defined plating technology) are used to build small flying microhelicopters, which are commercially available from the Institute of Microtechnology in Mainz, Germany, as rather expensive demonstration objects [27.114]. Besides the pure mechanical microrobots, hybrid systems consisting of electromechanical components and living organisms such as cockroaches have also been reported [27.117].

27.7.2 Bio-Microrobotics

Biomaniipulation entails such operations as positioning, grasping, and injecting material into various locations in cells. Research topics in bio-microrobotics include the autonomous manipulation of single cells or molecules, the characterization of biomembrane mechanical properties using microrobotic systems with integrated vision and force sensing modules, and more. The objective is to obtain a fundamental understanding of single-cell biological systems and provide characterized mechanical models of biomembranes for deformable cell tracking during biomaniipulation and cell injury studies.

Existing biomaniipulation techniques can be classified into noncontact manipulation including laser trapping [27.118–121] and electrorotation [27.122–124], and contact manipulation, referred to as mechanical micromanipulation [27.125]. When laser trapping [27.118–121] is used for noncontact biomaniipulation, a laser beam is focused through a large-numerical-aperture objective lens, converging to form an optical trap in which the lateral trapping force moves a cell in suspension toward the center of the beam. The longitudinal trapping force moves the cell in the direction of the focal point. The optical trap levitates the cell and holds it in position. Laser traps can work in a well-controlled manner. However, two features make laser trapping techniques undesirable for automated cell injection. The high dissipation of visible light in aqueous solutions requires the use of high-energy light close to the UV spectrum, raising the possibility of damage to the cell. Even though some researchers claim that such concerns could be overcome using wavelengths in the near-infrared (IR) spectrum [27.120], the question as to whether the incident laser beam might induce abnormalities in the cells' genetic material still exists. One alternative to using laser beams is the electrorotation technique. Electric-field-induced rotation of cells was demonstrated by *Mischel et al.* [27.126], *Arnold and Zimmermann* [27.127], and *Washizu et al.* [27.124]. This noncontact cell manipulation technique is based on controlling the phase shift and magnitude of electric fields. These fields, appropriately applied, produce a torque on the cell. Different system configurations

have been established for cell manipulation based on this principle [27.122, 123], which can achieve high accuracy in cell positioning. However, it lacks a means to hold the cell in place for further manipulation, such as injection, since the magnitude of the electric fields has to be kept low to ensure the viability of cells. The limits of noncontact biomaniipulation in the laser trapping and electrorotation techniques make mechanical micromanipulation desirable. The damage caused by laser beams in the laser trapping technique and the lack of a holding mechanism in the electrorotation technique can be overcome by mechanical micromanipulation.

To improve the low success rate of manual operation, and to eliminate contamination, an autonomous robotic system (shown in Fig. 27.9) has been developed to deposit DNA into one of the two nuclei of a mouse embryo without inducing cell lysis [27.11, 128]. The laboratory's experimental results show that the success rate for the autonomous embryo pronuclei DNA injection is dramatically improved over conventional manual

Fig. 27.9 Robotic biomaniipulation system with vision and force feedback

Fig. 27.10 Cell injection process. (a) Before and (b) during the injection of a mouse oocyte zona pellucida (ZP)

injection methods. The autonomous robotic system features a hybrid controller that combines visual servoing and precision position control, pattern recognition for detecting nuclei, and a precise autofocus scheme. Figure 27.10 illustrates the injection process.

To realize large-scale injection operations, a MEMS cell holder was fabricated using anodic wafer-bonding techniques. Arrays of holes are aligned on the cell holder, which are used to contain and fix individual cells for injection. When well calibrated, the system with the cell holder makes it possible to inject large numbers of cells using position control. The cell injection operation can be conducted in a move–inject–move manner.

A successful injection is determined greatly by injection speed and trajectory, and the forces applied to cells. To further improve the robotic system's performance, a multi-axial MEMS-based capacitive cellular force sensor is being designed and fabricated to provide realtime force feedback to the robotic system. The MEMS cellular force sensor also aids research in biomembrane mechanical property characterization.

MEMS-Based Multi-Axis Capacitive Cellular Force Sensor

The MEMS-based two-axis cellular force sensor [27.129] shown in Fig. 27.11 is capable of resolving normal forces applied to a cell as well as tangential forces generated by improperly aligned cell probes. A high-yield microfabrication process was developed to form the 3-D high-aspect-ratio structure using deep reactive ion etching (DRIE) on silicon-on-insulator (SOI) wafers. The constrained outer frame and the inner movable structure are connected by four curved springs. A load applied to the probe causes the inner structure to move, changing the gap between each pair of interdigitated comb capacitors. Consequently, the total capacitance change resolves the applied force. The interdigitated capacitors are orthogonally configured to make the force sensor capable of resolving forces in both the x - and y -directions. The cellular force sensors used in the experiments are capable of resolving forces up to $25 \mu\text{N}$ with a resolution of $0.01 \mu\text{N}$.

Tip geometry affects the quantitative force measurement results. A standard injection pipette (Cook K-MPIP-1000-5) tip section with a tip diameter of $5 \mu\text{m}$ is attached to the probe of the cellular force sensors.

The robotic system and high-sensitivity cellular force sensor are also applied to biomembrane mechanical property studies [27.130]. The goal is to obtain a general parameterized model describing cell membrane deformation behavior when an external load is applied. This parameterized model serves two chief purposes. First, in robotic biomanipulation, it allows online parameter recognition so that cell membrane deformation behavior can be predicted. Second, for a thermodynamic model of membrane damage in cell injury and recovery studies, it is important to appreciate the mechanical behavior of the membranes. This allows the interpretation of such reported phenomena as mechanical resistance to cellular volume reduction during dehydration, and its relationship to injury. The establishment of such a biomembrane model will greatly facilitate cell injury studies.

Experiments demonstrate that robotics and MEMS technology can play important roles in biological studies such as automating biomanipulation tasks. Aided by robotics, the integration of vision and force sensing modules, and MEMS design and fabrication techniques, investigations are being conducted in biomembrane mechanical property modeling, deformable cell tracking, and single-cell and biomolecule manipulation.

27.7.3 Bio-Mimetic/Untethered Microrobots

Similar to the larger scale, bio-mimicking is a significant approach for the design of micro- and nanorobots. However, at the micro-/nanoscale, the objectives we are learning from are not animals, fishes, birds, or insects anymore, rather we learn from such categories as bacteria, molecular motors, DNA molecules, and so on.

For instance, it is well known that a variety of microorganisms swim in liquid using flagella, a swimming strategy that is particularly well suited to their low-Reynolds-number regime [27.131]. Eukaryotic flagella

Fig. 27.11 A cellular force sensor with orthogonal comb drives detailed

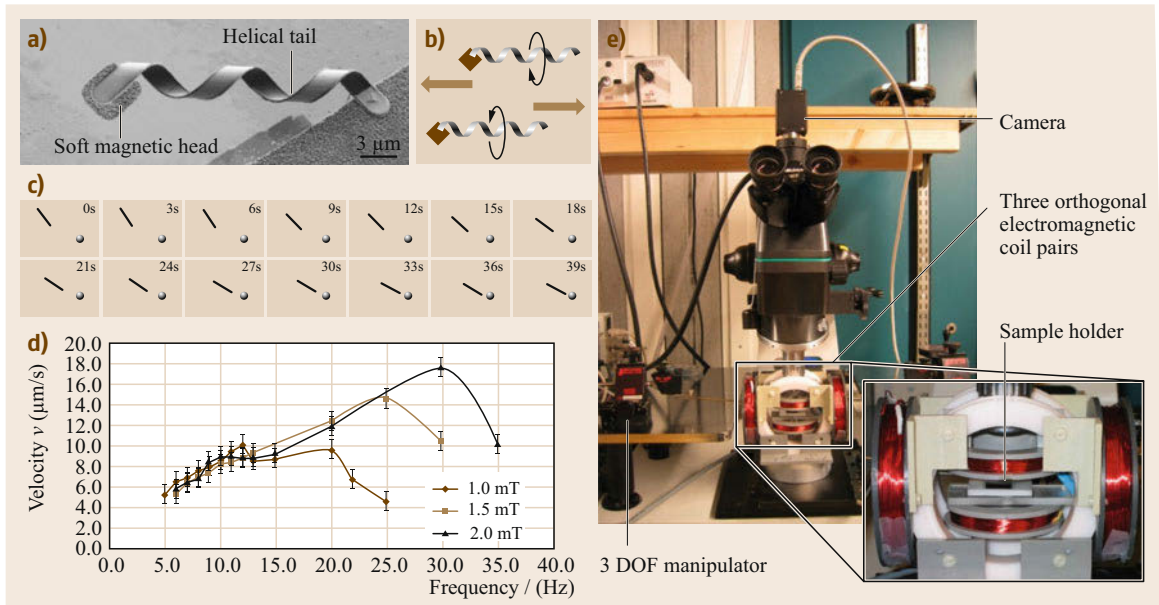

Fig. 27.12a–e Artificial bacteria flagella. (a) SEM micrograph of an as-fabricated ABF with a diameter of $2.7\ \mu\text{m}$. (b) Schematic drawing of driving an ABF swims forward and backward using a rotary-to-linear motion converter. For forward and backward motion, the helical tail turns clockwise (CW) and counterclockwise (CCW), respectively (as seen by an observer in front of the ABF). (c) A series of frames taken from a video camera showing an ABF swim forward in water. The ABF has an $81\ \mu\text{m}$ long InGaAs/GaAs/Cr helical tail, and a $4.5\ \mu\text{m} \times 4.5\ \mu\text{m}$ square head. B , f , θ , φ represent four parameters, i.e., magnetic field, field frequency, yaw and pitch, which can be controlled by the coil pairs. (d) The dependence of ABF velocity to frequency of external magnetic field generated by the coil pairs. (e) Experimental setup. All examples are from the authors' work

are active organelles that deform to create paddling motions, such as propagating waves or circular translating movements. Previous work experimentally demonstrated that this kind of motion can be approximated by a microscopic artificial swimmer consisting of a chain of DNA-bound magnetic beads connected to a red blood cell [27.132]. In contrast, bacterial (prokaryotic) flagella work differently by using a molecular motor to turn the base of a flagellum or bundle of flagella, which deform passively into a helical structure [27.133].

One example inspired by this is artificial bacterial flagella (ABFs) [27.134], which are proposed as microrobots capable of locomotion in liquid. An artificial bacterial flagellum consists of a helical tail resembling a natural flagellum, fabricated by the self-scrolling of helical nanobelts [27.135, 136], and a thin soft-magnetic head, consisting of a Cr/Ni/Au multilayer. Experimental investigation shows that an ABF can be propelled forward, backward and steered by a controlled external rotating magnetic field. ABFs have comparable swimming speed to bacteria propelled by flagella but under precise control.

An artificial bacterial flagellum (ABF) consists of two parts: a helical tail and a soft-magnetic metal

head as shown in Fig. 27.12. Previous work has shown that the geometrical shape of the helical tail, i.e., chirality, helicity angle and diameter, can be precisely controlled. To control the locomotion of the ABF remotely, three orthogonal electromagnetic coil pairs were employed to generate a uniform rotating magnetic field [27.137].

In principle, for forward and backward motion, the ABF acts as a corkscrew to convert rotary motion to linear motion as shown in Fig. 27.12b. Figure 27.12c shows a left-handed ABF swim controlled by coil pairs. It can be seen in Fig. 27.12c that the ABF swim forward until the 10th second by rotating the magnet field clockwise (CW). In contrast to a left-handed ABF, when the same field is applied to a right-handed ABF, though it rotates in the same direction as left-handed one, the swimming direction will be opposite. The magnetic torque for rotation is generated by the thin head attempting to align with the applied field, and torque for steering is generated by the diagonal axis of the square head attempting to align with the applied field, since the diagonal axis is the easy magnetization axis of thin square plates in weak applied fields. Thus, to steer the ABFs in water, two more parameters were applied, i.e.,

yaw (θ) and pitch (φ), for the turning and tilting of the ABF.

The velocity of ABF is investigated as a function of magnetic field strength and rotation frequency in water (Fig. 27.12d). A 45 μm long ABF is used for the tests with three different field strengths: 1.0 mT, 1.5 mT and 2.0 mT. The field's rotational frequency is increased from 5 Hz to 35 Hz. The results show that at low frequency the swimmer's rotation is synchronized with the applied field, and ABF velocity increases linearly with frequency, as expected in the low-Reynolds-number regime [27.131]. After reaching a maximum value, the velocity reduces and becomes less deterministic with increasing field frequency, since the available magnetic torque is no longer sufficient to keep the swimmer synchronized with the applied field. The fluctuations in the curves are attributed to unmodeled boundary conditions, such as wall effects and intermolecular interactions of the ABF with the substrate. The maximum velocity we have achieved is 18 $\mu\text{m/s}$, which is comparable to bacteria, such as *Escherichia coli* [27.138],

which swim by rotating their flagella with a frequency of about 100 Hz at room temperature. The results also indicate that by exerting a stronger magnetic torque on the ABF, higher driving frequencies can be achieved resulting in higher linear velocity. By extrapolating experimental results, if a frequency of 100 Hz can be achieved, the resulting swimming speed of ABFs may be beyond bacteria swimming speeds.

Self-propelled devices such as these are of interest in fundamental research and biomedical applications for mimicking and understanding natural organisms, for signaling inter- or intra-cellular information, for manipulating cellular or sub-cellular objects, and for targeted drug delivery. In contrast to bacteria that are propelled by nature flagella and move somewhat randomly in liquid, ABF motion can be precisely controlled by magnetic fields. ABFs can be used as a test bed for understanding the swimming behavior of bacteria and other swimming microorganisms, and can potentially be used for targeted drug delivery and as wireless manipulators for medical and biological applications.

27.8 Nanorobotics

Nanorobotics represents the next stage in miniaturization for maneuvering nanoscale objects. Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size, i.e., nanorobots, and large robots capable of manipulating objects that have dimensions in the nanoscale range with nanometer resolution, i.e., nanorobotic manipulators. Robotic manipulation at nanometer scales is a promising technology for structuring, characterizing, and assembling nanoscale building blocks into NEMS. Combined with recently developed nanofabrication processes, a hybrid approach is realized to build NEMS and other nanorobotic devices from individual carbon nanotubes and SiGe/Si nanocoils. Material science, biotechnology, electronics, and mechanical sensing and actuation will benefit from advances in nanorobotics.

27.8.1 Introduction

Nanomanipulation, or positional and/or force control at the nanometer scale, is a key enabling technology for nanotechnology by filling the gap between top-down and bottom-up strategies, and may lead to the appearance of replication-based molecular assemblers [27.18]. These types of assemblers have been proposed as general-purpose manufacturing devices for building a wide range of useful products as well as copies of themselves (self-replication).

Presently, nanomanipulation can be applied to the scientific exploration of mesoscopic physical phenomena, biology, and the construction of prototype nanodevices. It is a fundamental technology for property characterization of nanomaterials, nanostructures, and nanomechanisms, for the preparation of nanoscale building blocks, and for the assembly of nanodevices such as NEMS.

Nanomanipulation was enabled by the inventions of the STM [27.19], AFMs [27.44], and other types of scanning probe microscopes (SPMs). Besides these, optical tweezers (laser trapping) [27.139] and magnetic tweezers [27.140] are also potential nanomanipulators. Nanorobotic manipulators (NRMs) [27.141, 142] are characterized by the capability of 3-D positioning, orientation control, independently actuated multiple end-effectors, and independent real-time observation systems, and can be integrated with scanning probe microscopes. NRMs largely extend the complexity of nanomanipulation.

A concise comparison of STM, AFM, and NRM technology is shown in Fig. 27.13. With its incomparable imaging resolution, an STM can be applied to particles as small as atoms with atomic resolution. However, limited by its 2-D positioning and available strategies for manipulations, standard STMs are ill-suited for complex manipulation and cannot be used in 3-D space. An AFM is another important type of nanomanipulator. Manipulation with an AFM can

be done in either contact or dynamic mode. Generally, manipulation with an **AFM** involves moving an object by touching it with a tip. A typical manipulation starts by imaging a particle in noncontact mode, then removing the tip oscillation voltage and sweeping the tip across the particle in contact with the surface and with the feedback disabled. Mechanical pushing can exert larger forces on objects and, hence, can be applied for the manipulation of relatively larger objects. 1- to 3-D objects can be manipulated on a 2-D substrate. However, the manipulation of individual atoms with an **AFM** remains a challenge. By separating the imaging and manipulation functions, nanorobotic manipulators can have many more degrees of freedom including rotation for orientation control, and hence can be used for the manipulation of 0-D (symmetric spheres) to 3-D objects in 3-D free space. Limited by the lower resolution of electron microscopes, **NRM**s are difficult to use for the manipulation of atoms. However, their general robotic capabilities, including 3-D positioning, orientation control, independently actuated multiple endeffectors, separate real-time observation system, and integration with SPMs inside, make **NRM**s quite promising for complex nanomanipulation.

The first nanomanipulation experiment was performed by *Eigler and Schweizer* in 1990 [27.143]. They used an **STM** and materials at low temperatures (4 K) to position individual xenon atoms on a single-crystal nickel surface with atomic precision. The manipulation enabled them to fabricate rudimentary structures of their own design, atom by atom. The result is the famous set of images showing how 35 atoms were moved to form the three-letter logo *IBM*, demonstrating that matter could indeed be maneuvered atom by atom as *Feynman* suggested [27.1].

A nanomanipulation system generally includes nanomanipulators as the positioning device, microscopes as *eyes*, various end-effectors including probes and tweezers among others as its *fingers*, and various types of sensors (force, displacement, tactile, strain, etc.) to facilitate the manipulation and/or to determine the properties of the objects. Key technologies for nanomanipulation include observation, actuation, measurement, system design and fabrication, calibration and control, communication, and the human-machine interface.

Strategies for nanomanipulation are basically determined by the environment – air, liquid or vacuum – which is further decided by the properties and size of the objects and observation methods. Figure 27.14 depicts the microscopes, environments, and strategies of nanomanipulation. In order to observe manipulated objects, **STMs** can provide sub-Ångström imaging res-

Fig. 27.13 Comparison of nanomanipulators

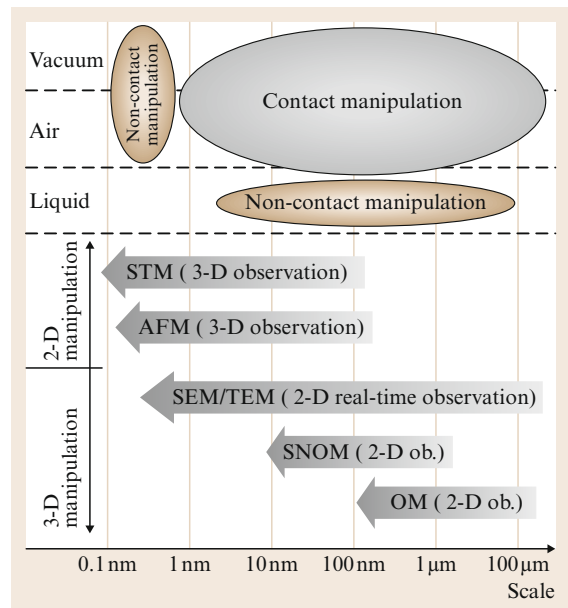

Fig. 27.14 Microscopes, environments, and strategies of nanomanipulation

olution, whereas **AFMs** can provide atomic resolutions. Both can obtain 3-D surface topology. Because **AFMs** can be used in an ambient environment, they provide a powerful tool for biomanipulation that may require a liquid environment. The resolution of **SEM** is limited to about 1 nm, whereas field-emission **SEM** (**FESEM**) can achieve higher resolutions. **SEM/FESEM** can be used for real-time 2-D observation for both the objects and end-effectors of manipulators, and large ultrahigh-vacuum (**UHV**) sample chambers provide enough space to contain an **NRM** with many degrees of freedom

(DOFs) for 3-D nanomanipulation. However, the 2-D nature of the observation makes positioning along the electron-beam direction difficult. High-resolution transmission electron microscopes (HRTEM) can provide atomic resolution. However, the narrow UHV specimen chamber makes it difficult to incorporate large manipulators. In principle, optical microscopes (OMs) cannot be used for nanoscale (smaller than the wavelength of visible lights) observation because of diffraction limits. Scanning near-field OMs (SNOMs) break this limitation and are promising as a real-time observation device for nanomanipulation, especially for ambient environments. SNOMs can be combined with AFMs, and potentially with NRMs for nanoscale biomanipulation.

Nanomanipulation processes can be broadly classified into three types:

1. Lateral noncontact
2. Lateral contact
3. Vertical manipulation.

Generally, lateral noncontact nanomanipulation is mainly applied for atoms and molecules in UHV with an STM or bio-object in liquid using optical or magnetic tweezers. Contact nanomanipulation can be used in almost any environment, generally with an AFM, but is difficult for atomic manipulation. Vertical manipulation can be performed by NRMs. Figure 27.15 shows the processes of the three basic strategies.

Motion of the lateral noncontact manipulation processes is shown in Fig. 27.15a. Applicable effects [27.144] able to cause the motion include long-range van der Waals (vdW) forces (attractive) generated by the proximity of the tip to the sample [27.145], electric-field-induced fields by the voltage bias between the tip and the sample [27.146, 147], tunneling current local heating or inelastic tunneling vibration [27.148, 149]. With these methods, some nanodevices and molecules have been assembled [27.150, 151]. Laser trapping (optical tweezers) and magnetic tweezers are possible for noncontact manipulation of nanoscale biosamples, e.g., DNA [27.152, 153].

Noncontact manipulation combined with STMs has revealed many possible strategies for manipulating atoms and molecules. However, for the manipulation of carbon nanotubes (CNTs) no examples have been demonstrated.

Pushing or pulling nanometer objects on a surface with an AFM is a typical manipulation using this method as shown in Fig. 27.15b. Early work showed the effectiveness of this method for the manipulation of nanoparticles [27.154–158]. This method has also been shown in nanoconstruction [27.159] and biomanipulation [27.160]. A virtual-reality interface facilitates such manipulation [27.161–163] and may create an opportunity for other types of manipulation. This technique has been used in the manipulation of nanotubes on a surface, and some examples will be introduced later in this chapter.

The pick-and-place task as shown in Fig. 27.15c is especially significant for 3-D nanomanipulation since its main purpose is to assemble prefabricated building blocks into devices. The main difficulty is in achieving sufficient control of the interaction between the tool and object and between the object and the substrate. Two strategies have been presented for micromanipulation [27.164] and have also proven to be effective for nanomanipulation [27.142]. One strategy is to apply

Fig. 27.15a–c Basic strategies of nanomanipulation. In the figure, A, B, C,... represent the positions of end-effector (e.g., a tip); A', B', C',... the positions of objects; 1, 2, 3,... the motions of end-effector; and 1', 2', 3',... the motions of objects. Tweezers can be used in pick-and-place to facilitate the picking-up, but are generally not necessarily helpful for placing. (a) Lateral noncontact nanomanipulation (sliding). (b) Lateral contact nanomanipulation (pushing/pulling). (c) Vertical nanomanipulation (picking and placing)

a dielectrophoretic force between a tool and an object as a controllable additional external force by applying a bias between the tool and the substrate on which the object is placed. Another strategy is to modify the van der Waals and other intermolecular and surface forces between the object and the substrate. For the former, an AFM cantilever is ideal as one electrode to generate a nonuniform electrical field between the cantilever and the substrate.

27.8.2 Nanorobotic Manipulation Systems

Nanorobotic manipulators are the core components of nanorobotic manipulation systems. The basic requirements for a nanorobotic manipulation system for 3-D manipulation include nanoscale positioning resolution, a relative large working space, enough DOFs includ-

ing rotational ones for 3-D positioning and orientation control of the end-effectors, and usually multiple end effectors for complex operations.

A commercially available nanomanipulator (MM3A from Kleindiek) installed inside an SEM (Carl Zeiss DSM962) is shown in Fig. 27.16. The manipulator has three degrees of freedom, and nanometer-to subnanometer-scale resolution (Table 27.4). Calculations show that when moving/scanning in the A/B direction at joint q_1/q_2 , the additional linear motion in C is very small. For example, when the arm length is 50 mm, the additional motion in the C direction is only 0.25 nm to 1 nm when moving 5–10 μm ; in the A direction; these errors can be ignored or compensated with an additional motion of the prismatic joint p_3 , which has a 0.25 nm resolution.

Figure 27.17a shows a nanorobotic manipulation system that has 16 DOFs in total and can be equipped with three or four AFM cantilevers as end-effectors for both manipulation and measurement. The positioning resolution is sub-nanometer and strokes are on the order

Fig. 27.16 (a) Nanomanipulator MM3A from Kleindiek (b) inside an SEM (c) kinematic model

Table 27.4 Specifications of MM3A

Item	Specification
Operating range q_1 and q_2	240°
Operating range Z	12 mm
Resolution A (horiz.)	10 ⁻⁷ rad (5 nm)
Resolution B (vert.)	10 ⁻⁷ rad (3.5 nm)
Resolution C (linear)	0.25 nm
Fine (scan) range A	20 μm
Fine (scan) range B	15 μm
Fine (scan) range C	1 μm
Speed A, B	10 mm/s
Speed C	2 mm/s

of centimeters. The manipulation system is not only for nanomanipulation, but also for nanoassembly, nanoinstrumentation, and nanofabrication. Four-probe semiconductor measurements are perhaps the most complex manipulation that this system can perform, because it is necessary to actuate four probes independently by using four manipulators. With the advancement of nanotechnology, one could shrink the size of nanomanipulators and insert more DOFs inside the limited vacuum chamber of a microscope, and perhaps the molecular version of manipulators such as that dreamed of by Drexler could be realized [27.18].

For the construction of multi-walled carbon nanotube (MWNT)-based nanostructures, manipulators position and orient nanotubes for the fabrication of nanotube probes and emitters, for performing nanosoldering with electron-beam-induced deposition (EBID) [27.165], for the property characterization of single nanotubes for selection purposes and for characterizing junctions to test connection strength.

A nanolaboratory is shown in Fig. 27.17b. The nanolaboratory integrates a nanorobotic manipulation system with a nanoanalytical system and a nanofabrication system, and can be applied for manipulating nanomaterials, fabricating nanoscale building blocks, assembling nanodevices, and for in situ analysis of the properties of such materials, building blocks, and devices. Nanorobotic manipulation within the nanolaboratory has opened a new path for constructing nanosystems in 3-D space, and will create opportunities for new nanoinstrumentation and nanofabrication processes.

27.8.3 Nanorobotic Manipulation and Assembly

Nanomanipulation is a promising strategy for nanoassembly. Key techniques for nanoassembly include the structuring and characterization of nanoscale building blocks, the positioning and orientation control of the building blocks with nanoscale resolution, and effective connection techniques. Nanorobotic manipulation, which is characterized by multiple DOFs with both position and orientation controls, independently actuated multiprobes, and a real-time observation system, have been shown effective for assembling nanotube-based devices in 3-D space.

The well-defined geometries, exceptional mechanical properties, and extraordinary electric characteristics, among other outstanding physical properties of CNTs [27.166] qualify them for many potential applications, especially in nanoelectronics [27.167], NEMS, and other nanodevices [27.168]. For NEMS, some of the most important characteristics of nanotubes

include their nanometer diameter, large aspect ratio (10–1000), TPa-scale Young's modulus [27.169–171], excellent elasticity [27.141], ultralow interlayer friction, excellent capability for field emission, various electric conductivities [27.172], high thermal conductivity [27.173], high current-carrying capability with essentially no heating [27.174], sensitivity of conductance to various physical or chemical changes, and charge-induced bond-length change.

Helical 3-D nanostructures, or nanocoils, have been synthesized from various materials, including helical carbon nanotubes [27.175] and zinc oxide nanobelts [27.176]. A new method of creating structures with nanoscale dimensions has recently been presented [27.177] and can be fabricated in a controllable way [27.178, 179]. The structures are created through a top-down fabrication process in which a strained nanometer-thick heteroepitaxial bilayer curls up to form 3-D structures with nanoscale features. Helical geometries and tubes with diameters between 10 nm and 10 μm have been achieved. Because of their interesting morphology, mechanical, electrical, and electromagnetic properties, potential applications of these nanostructures in NEMS include nanosprings [27.180], electromechanical sensors [27.181], magnetic field detectors, chemical or biological sensors, generators of magnetic beams, inductors, actuators, and high-performance electromagnetic wave absorbers.

NEMS based on individual carbon nanotubes and nanocoils are of increasing interest, indicating that capabilities for incorporating these individual building blocks at specific locations on a device must be developed. Random spreading [27.182], direct growth [27.183], self-assembly [27.184], dielectrophoretic assembly [27.185, 186], and nanomanipulation [27.187] have been demonstrated for positioning as-grown nanotubes on electrodes for the construction of these devices. However, for nanotube-based structures, nanorobotic assembly is still the only technique capable of in situ structuring, characterization, and assembly. Because the as-fabricated nanocoils are not free-standing from their substrate, nanorobotic assembly is virtually the only way to incorporate them into devices at present.

Nanorobotic Assembly of Carbon Nanotubes

Nanotube manipulation in two dimensions on a surface was first performed with an AFM by contact pushing on a substrate. Figure 27.18 shows the typical methods for 2-D pushing. Although similar to that shown in Fig. 27.15b, the same manipulation caused various results because nanotubes cannot be regarded as a 0-D point. The first demonstration was given by Wong et al. for measuring the mechanical properties of

a nanotube [27.188]. They adopt the method shown in Fig. 27.18b, i.e., to bend a nanotube by pushing one end of it and fixing the other end. The same strategy was used for the investigation of the behavior of nanotubes under large strain [27.189]. Postma et al. applied the strategies shown in Fig. 27.18c,d to obtain a kinked junction and crossed nanotubes [27.190]. Hertel et al. combined this technique with an inverse process, namely straightening by pushing along a bent tube, and realized the translation of the tube to another location [27.191] and between two electrodes to measure the conductivity [27.192]. This technique was also used to place a tube on another tube to form a single-electron transistor (SET) with a cross-junction of nanotubes [27.193]. Pushing-induced breaking (Fig. 27.18d) has also been demonstrated for a nanotube [27.191]. The simple assembly of two bent tubes and a straight one formed a Greek letter θ . To investigate the dynamics of rolling at the atomic level, rolling and sliding of a nanotube (as shown in Fig. 27.18e,f) are performed on graphite surfaces using an AFM [27.194]. Besides pushing and pulling, another important process is indentation. By indenting a surface, mechanical property characterization [27.195] and data storage [27.196] can be realized.

Manipulation of CNTs in 3-D space is important for assembling CNTs into structures and devices. Basic techniques for the nanorobotic manipulation of carbon nanotubes are shown in Fig. 27.19 [27.197]. These serve as the basis for handling, structuring, characterizing, and assembling NEMS.

The basic procedure is to pick up a single tube from nanotube soot (Fig. 27.19a). This has been shown first by using dielectrophoresis [27.142] through nanorobotic manipulation (Fig. 27.19b). By applying a bias between a sharp tip and a plane substrate, a nonuniform electric field can be generated between the tip and the substrate with the strongest field near the tip. This field can cause a tube to orient along the field or further *jump* to the tip by electrophoresis or dielectrophoresis (determined by the conductivity of objective tubes). Removing the bias, the tube can be placed at other locations at will. This method can be used for free-standing tubes on nanotube soot or on a rough surface on which surface van der Waals forces are generally weak. A tube strongly rooted in CNT soot or lying on a flat surface cannot be picked up in this way. The interaction between a tube and the atomic flat surface of AFM cantilever tip has been shown to be strong enough for picking up a tube onto the tip [27.198] (Fig. 27.19c). By using EBID, it is possible to pick up and fix a nanotube onto a probe [27.199] (Fig. 27.19d). For handling a tube, weak connection between the tube and the probe is desired.

Fig. 27.18a–f Two-dimensional manipulation of CNTs. Starting from the original state shown in (a), pushing the tube at different site with different force may cause the tube to deform as in (b) and (c), to break as in (d), or to move as in (e) and (f). (a) Original state. (b) Bending. (c) Kinking. (d) Breaking. (e) Rolling. (f) Sliding

Bending and buckling a CNT as shown in Fig. 27.19e,f are important for in situ property characterization of a nanotube [27.200], which is a simple way to obtain the Young's modulus of a nanotube without damaging the tube (if performed within its elastic range) and hence can be used for the selection of a tube with desired properties. By buckling an MWNT over its elastic limit, a kinked structure can be obtained [27.201]. To obtain any desired angle for a kinked junction it is possible to fix the shape of a buckled nanotube within its elastic limit by using EBID [27.202]. For a CNT, the maximum angular displacement will appear at the fixed left end under pure bending or at the middle point under pure buckling. A combination of these two kinds of loads will achieve a controllable position of the kinked point and a desired kink angle. If the deformation is within the elastic limit of the nanotube, it will recover as the load is released. To avoid this, EBID can be applied at the kinked point to fix the shape.

Stretching a nanotube between two probes or a probe and a substrate has generated several interesting results (Fig. 27.19g). The first demonstration of 3-D nanomanipulation of nanotubes took this as an example to show the breaking mechanism and to measure the tensile strength of CNTs [27.141]. By breaking an MWNT in a controlled manner, interesting nanodevices have been fabricated. This technique – destructive fabrication – has been presented to get sharpened and lay-

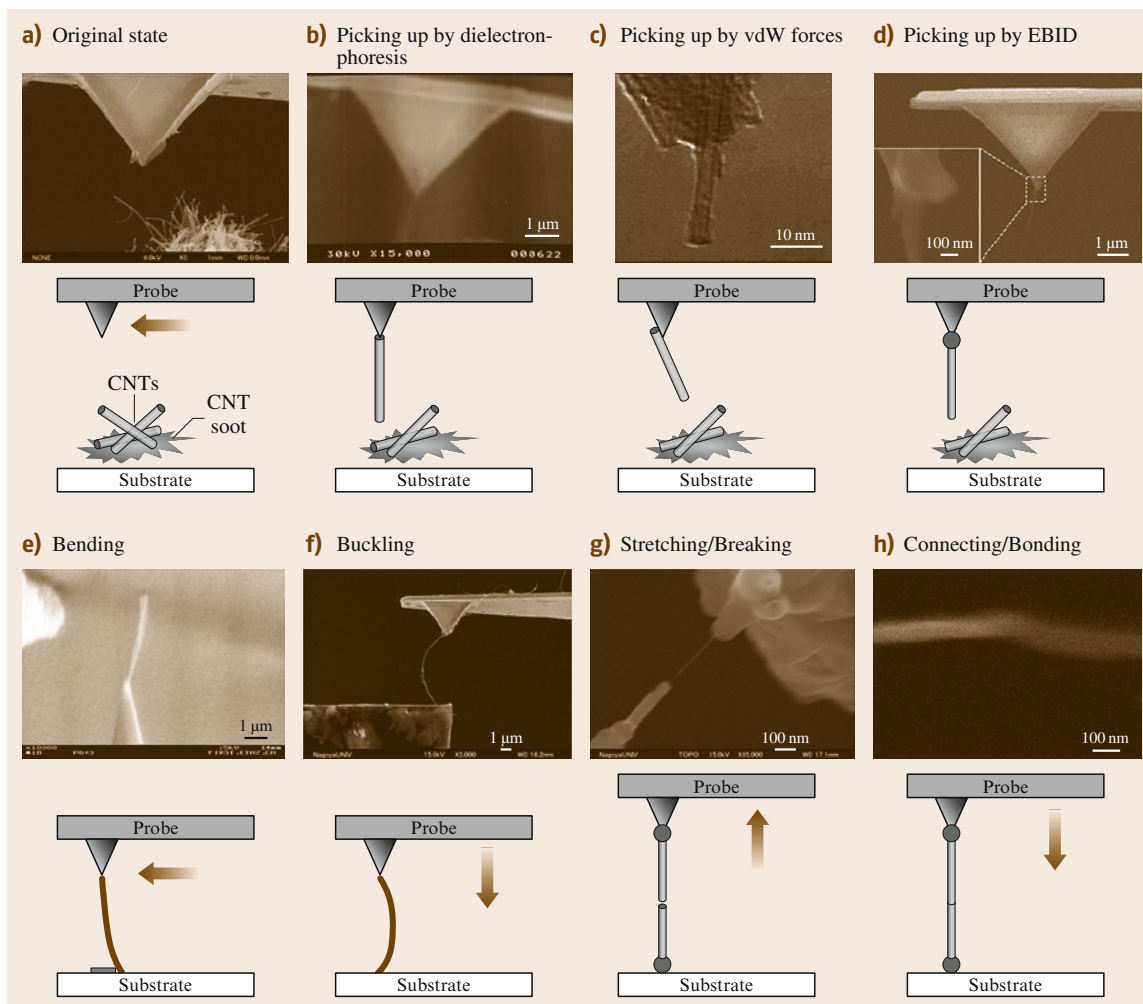

Fig. 27.19a–h Nanorobotic manipulation of CNTs. The basic technique is to pick up an individual tube from CNT soot (as in (a)) or from an oriented array; (b) shows a free-standing nanotube picked up by dielectrophoresis generated by a nonuniform electric field between the probe and substrate, (c) (after [27.196]) and (d) show the same manipulation by contacting a tube with the probe surface or fixing (e.g., with EBID) a tube to the tip (inset shows the EBID deposit). Vertical manipulation of nanotubes includes bending (e), buckling (f), stretching/breaking (g), and connecting/bonding (h). All examples with the exception of (i) are from the authors' work

ered structures of nanotubes, and to improve the length control of a nanotube [27.201]. Typically, a layered and a sharpened structure can be obtained from this process, similar to that achieved from electric pulses [27.202]. Bearing motion has also been observed in an incompletely broken MWNT [27.201]. The interlayer friction has been shown to be very small [27.203, 204].

The reverse process, namely the connection of broken tubes (Fig. 27.19h), has been demonstrated recently, and the mechanism is revealed as rebonding of unclosed dangling bonds at the ends of broken tubes [27.205]. Based on this interesting phenomenon,

mechanochemical nanorobotic assembly has been performed [27.206].

Assembly of nanotubes is a fundamental technology for enabling nanodevices. The most important tasks include the connection of nanotubes and placing of nanotubes onto electrodes. Pure nanotube circuits [27.206] created by interconnecting nanotubes of different diameters and chirality could lead to further size reductions in devices. Nanotube intermolecular and intramolecular junctions are basic elements for such systems [27.207]. Room-temperature (RT) single-electron transistors (SETs) [27.208] have been shown

with a short (≈ 20 nm) nanotube section that is created by inducing local barriers into the tube with an AFM, and Coulomb charging has been observed. With a cross-junction of two single-walled carbon nanotubes (SWNTs) (semiconducting/metallic), three- and four-terminal electronic devices have been made [27.209]. A suspended cross-junction can function as an electromechanical nonvolatile memory [27.210].

Although some kinds of junctions have been synthesized with chemical methods, there is no evidence yet showing that a self-assembly-based approach can provide more complex structures. SPMs were also used to fabricate junctions, but they are limited to a 2-D plane. We have presented 3-D nanorobotic manipulation-based nanoassembly, which is a promising strategy both for the fabrication of nanotube junctions and for the construction of more complex nanodevices with such junctions as well.

Nanotube junctions can be classified into different types by the kinds of components (SWNTs or MWNTs), geometric configurations (V kink, I, X cross, T, Y branch, and 3-D junctions) conductivity (metallic or semiconducting), and connection methods (intermolecular (connected with van der Waals force, EBID, etc.) or intramolecular (connected with chemical bonds) junctions). Here we show the fabrication of several kinds of MWNT junctions by emphasizing the connection methods. These methods will also be effective for SWNT junctions. Figure 27.20 shows CNT junctions constructed by connecting with van der Waals forces (a), joining by electron-beam-induced deposition (b), and bonding through mechanochemistry (c).

Figure 27.20a shows a T-junction connected with van der Waals forces, which is fabricated by positioning the tip of an MWNT onto another MWNT until they form a bond. The contact is checked by measuring the shear connection force.

EBID provides a soldering method to obtain stronger nanotube junctions than those connected through van der Waals forces. Hence, if the strength of nanostructures is emphasized, EBID can be applied. Figure 27.20b shows an MWNT junction connected through EBID, in which the upper MWNT is a single one with 20 nm in diameter and the lower one is a bundle of MWNTs with an extruded single CNT with $\varnothing 30$ nm. The development of conventional EBID has been limited by the expensive electron filament used and low productivity. We have presented a parallel EBID system by using CNTs as emitters because of their excellent field-emission properties [27.211]. The feasibility of parallel EBID is presented. It is a promising strategy for large-scale fabrications of nanotube junctions. As in its macroscale counterpart, welding, EBID works by adding materials to obtain stronger

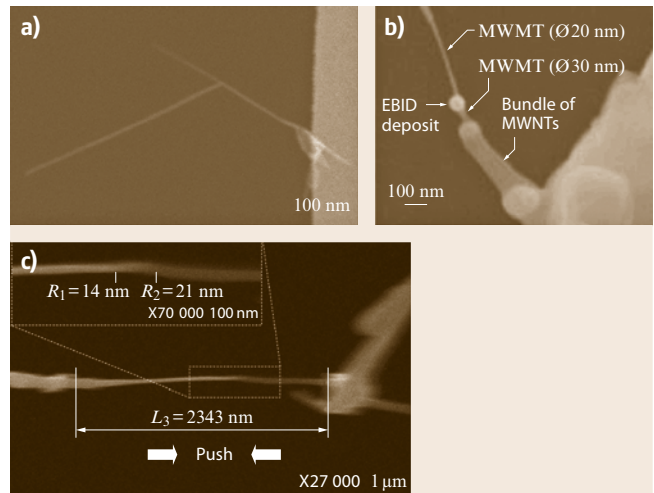

Fig. 27.20a–c MWNT junctions. (a) MWNTs connected with van der Waals forces. (b) MWNTs joined with EBID. (c) MWNTs bonded with a mechanochemical reaction

connections, but in some cases, the added material might influence normal functions for nanosystems. So, EBID is mainly applied to nanostructures rather than nanomechanisms.

To construct stronger junctions without adding additional materials, mechanochemical nanorobotic assembly is an important strategy. Mechanochemical nanorobotic assembly is based on solid-phase chemical reactions, or mechanosynthesis, which is defined as chemical synthesis controlled by mechanical systems operating with atomic-scale precision, enabling direct positional selection of reaction sites [27.18]. By picking up atoms with dangling bonds rather than natural atoms only, it is easier to form primary bonds, which provides a simple but strong connection. Destructive fabrication provides a way to form dangling bonds at the ends of broken tubes. Some of the dangling bonds may close with neighboring atoms, but generally a few bonds will remain dangling. A nanotube with dangling bonds at its end will bind more easily to another to form intramolecular junctions. Figure 27.20c shows such a junction.

Three-dimensional nanorobotic manipulation has opened a new route for the structuring and assembly of nanotubes into nanodevices. However, at present nanomanipulation is still performed in a serial manner with master–slave control, which is not a large-scale production-oriented technique. Nevertheless, with advances in the exploration of mesoscopic physics, better control on the synthesis of nanotubes, more accurate actuators, and effective tools for manipulation, high-speed and automatic nanoassembly will be possible. Another approach might be parallel assembly by positioning building blocks with an array of probes [27.212] and

joining them together simultaneously, e.g., with the parallel EBID [27.199] we presented. Further steps might progress towards exponential assembly [27.213], and in the far future to self-replicating assembly [27.18].

Nanorobotic Assembly of Nanocoils

The construction of nanocoil-based NEMS involves the assembly of as-grown or as-fabricated nanocoils, which is a significant challenge from a fabrication standpoint. Focusing on the unique aspects of manipulating nanocoils due to their helical geometry, high elasticity, single-end fixation, and strong adhesion of the coils to the substrate from wet etching, a series of new processes has been presented using a manipulator (MM3A, Kleindiek) installed in an SEM (Zeiss DSM962). As-fabricated SiGe/Si bilayer nanocoils (thickness 20 nm without Cr layer or 41 nm with Cr layer; diameter $D = 3.4 \mu\text{m}$) are manipulated. Special tools have been fabricated including a nanohook prepared by controlled *tip-crashing* of a commercially available tungsten sharp probe (Picoprobe T-4-10–1 mm and T-4-10) onto a substrate, and a *sticky* probe prepared by tip dipping into a double-sided SEM silver conductive tape (Ted Pella, Inc.). As shown in Fig. 27.21, experiments demon-

strate that nanocoils can be released from a chip by lateral pushing, picked up with a nanohook or a *sticky* probe, and placed between the probe/hook and another probe or an AFM cantilever (Nano-probe, NP-S). Axial pulling/pushing, radial compressing/releasing, and bending/buckling have also been demonstrated. These processes have shown the effectiveness of manipulation for the characterization of coil-shaped nanostructures and their assembly for NEMS, which have been otherwise unavailable.

Configurations of nanodevices based on individual nanocoils are shown in Fig. 27.22. Cantilevered nanocoils as shown in Fig. 27.22a can serve as nanosprings. Nanoelectromagnets, chemical sensors, and nanoinductors involve nanocoils bridged between two electrodes as shown in Fig. 27.22b. Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode as shown in Fig. 27.22c. Mechanical stiffness and electric conductivity are fundamental properties for these devices that must be further investigated.

As shown in Fig. 27.21h, axial pulling is used to measure the stiffness of a nanocoil. A series of SEM images are analyzed to extract the AFM tip displacement

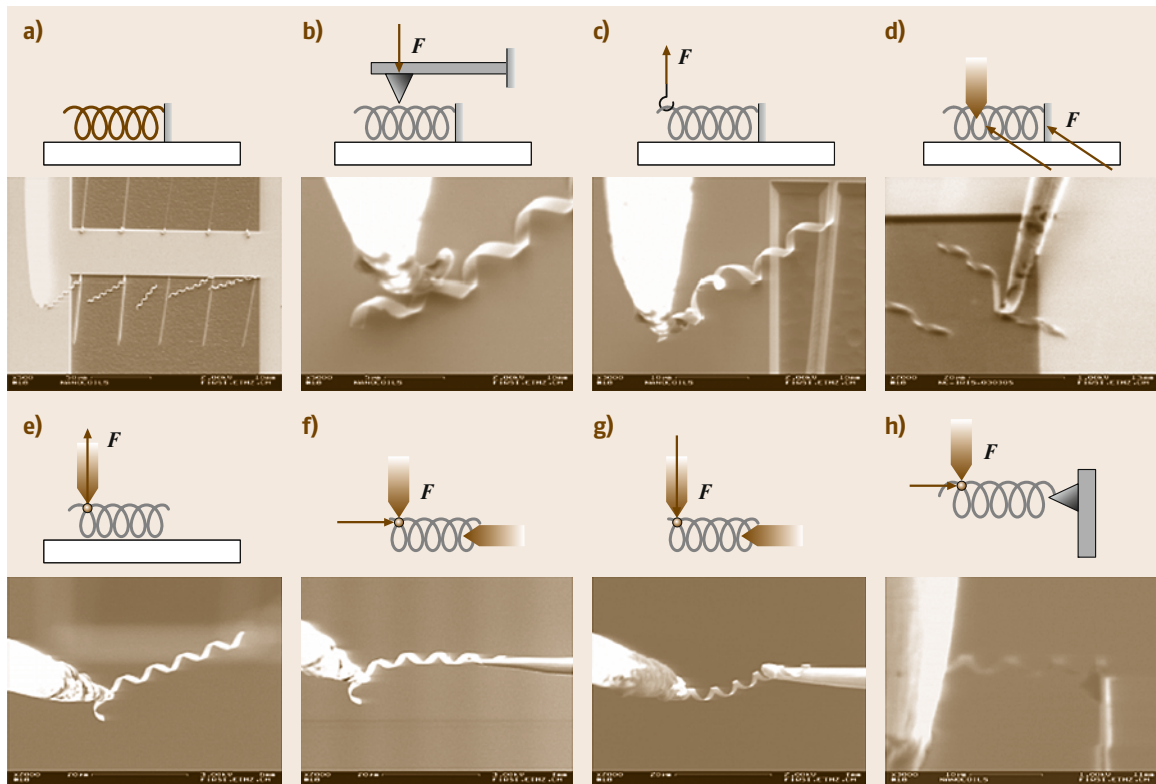

Fig. 27.21a–h Nanorobotic manipulation of nanocoils (a) original state, (b) compressing/releasing, (c) hooking, (d) lateral pushing/breaking, (e) picking, (f) placing/inserting, (g) bending, and (h) pushing and pulling

ment and the nanospring deformation, i. e., the relative displacement of the probe from the AFM tip. From this displacement data and the known stiffness of the AFM cantilever, the tensile force acting on the nanospring versus the nanospring deformation was plotted. The deformation of the nanospring was measured relative to the first measurement point. This was necessary because the proper attachment of the nanospring to the AFM cantilever must be verified. Afterwards, it was not possible to return to the point of zero deformation. Instead, the experimental data as presented in Fig. 27.22d has been shifted such that with the calculated linear elastic spring stiffness the line begins at zero force and zero deformation. From Fig. 27.22d, the stiffness of the spring was estimated to be 0.0233 N/m. The linear elastic region of the nanospring extends to a deformation of 4.5 μm . An exponential approximation was fitted to the nonlinear region. When the applied force reached 0.176 μN , the attachment between the nanospring and the AFM cantilever broke. Finite-element simulation (ANSYS 9.0) was used to validate the experimental data [27.181]. Since the exact region of attachment cannot be identified from the SEM images, simulations were conducted for 4, 4.5, and 5 turns to estimate the possible range according to the apparent number of turns of the nanospring. The nanosprings in the sim-

ulations were fixed at one end and had an axial load of 0.106 μN applied at the other end. The simulation results for the spring with four turns yield a stiffness of 0.0302 N/m; for the nanospring with 5 turns it is 0.0191 N/m. The measured stiffness falls within this range with 22.0% above the minimum value and 22.8% below the maximum value, and very close to the stiffness of a 4.5-turn nanospring, which has a stiffness of 0.0230 N/m according to the simulation.

Figure 27.22e shows the results from electrical characterization experiments on a nanospring with 11 turns using the configuration shown in Fig. 27.21g. The I - V curve is nonlinear, which may be caused by the resistance change of the semiconductive bilayer due to ohmic heating. Another possible reason is the decrease in contact resistance caused by thermal stress. The maximum current was found to be 0.159 mA under an 8.8 V bias. Higher voltage causes the nanospring to *blow off*. From the fast scanning screen of the SEM, an extension of the nanospring on probes was observed around the peak current so that the current does not drop abruptly. At 9.4 V, the extended nanospring is broken down, causing an abrupt drop in the I - V curve.

From fabrication and characterization results, the helical nanostructures appear to be suitable to function as inductors. They would allow further miniaturization

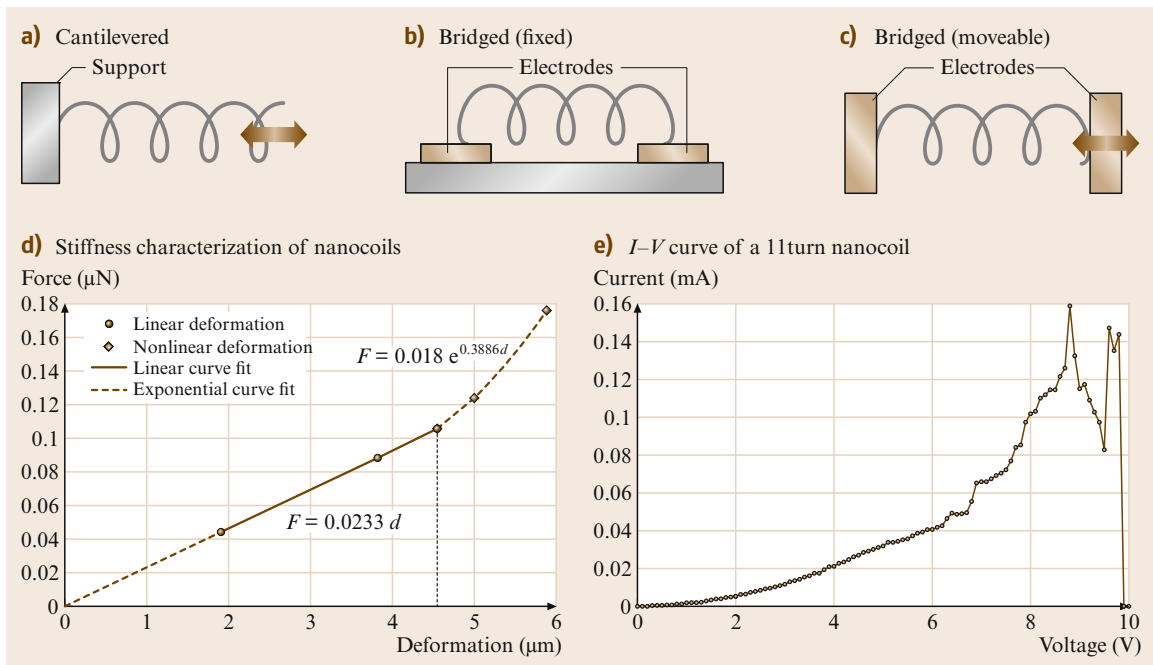

Fig. 27.22a-e Nanocoil-based devices. Cantilevered nanocoils (a) can serve as nanosprings. Nanoelectromagnets, chemical sensors, and nanoinductors involve nanocoils bridged between two electrodes (b). Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode (c). Mechanical stiffness (d) and electric conductivity (e) are basic properties of interest for these devices

compared to state-of-the-art microinductors. For this purpose, higher doping of the bilayer and an additional metal layer would result in the required conductance. Conductance, inductance, and quality factor can be further improved if, after curling up, additional metal is electroplated onto the helical structures. Moreover, a semiconductive helical structure, when functionalized with binding molecules, can be used for chemical sensing under the same principle as demonstrated with other types of nanostructures. With bilayers in the range of a few monolayers, the resulting structures would exhibit very high surface-to-volume ratio with the whole surface exposed to an incoming analyst.

27.8.4 Nanorobotic Systems

Nanorobotic devices involve tools, sensors, and actuators at the nanometer scale. Shrinking device size makes it possible to manipulate nanosized objects with nanosized tools, measure mass in femtogram ranges, sense

force at piconewton scales, and induce GHz motion, among other amazing advancements.

Top-down and bottom-up strategies for manufacturing such nanodevices have been independently investigated by a variety of researchers. Top-down strategies are based on nanofabrication and include technologies such as nanolithography, nanoimprinting, and chemical etching. Presently, these are 2-D fabrication processes with relatively low resolution. Bottom-up strategies are assembly-based techniques. At present, these strategies include such techniques as self-assembly, dip-pen lithography, and directed self-assembly. These techniques can generate regular nanopatterns at large scales. With the ability to position and orient nanoscale objects, nanorobotic manipulation is an enabling technology for structuring, characterizing and assembling many types of nanosystems [27.197]. By combining bottom-up and top-down processes, a hybrid nanorobotic approach based on nanorobotic manipulation provides a third way to fabricate NEMS by structuring as-grown nanomaterials or nanostructures. This new nanomanufacturing

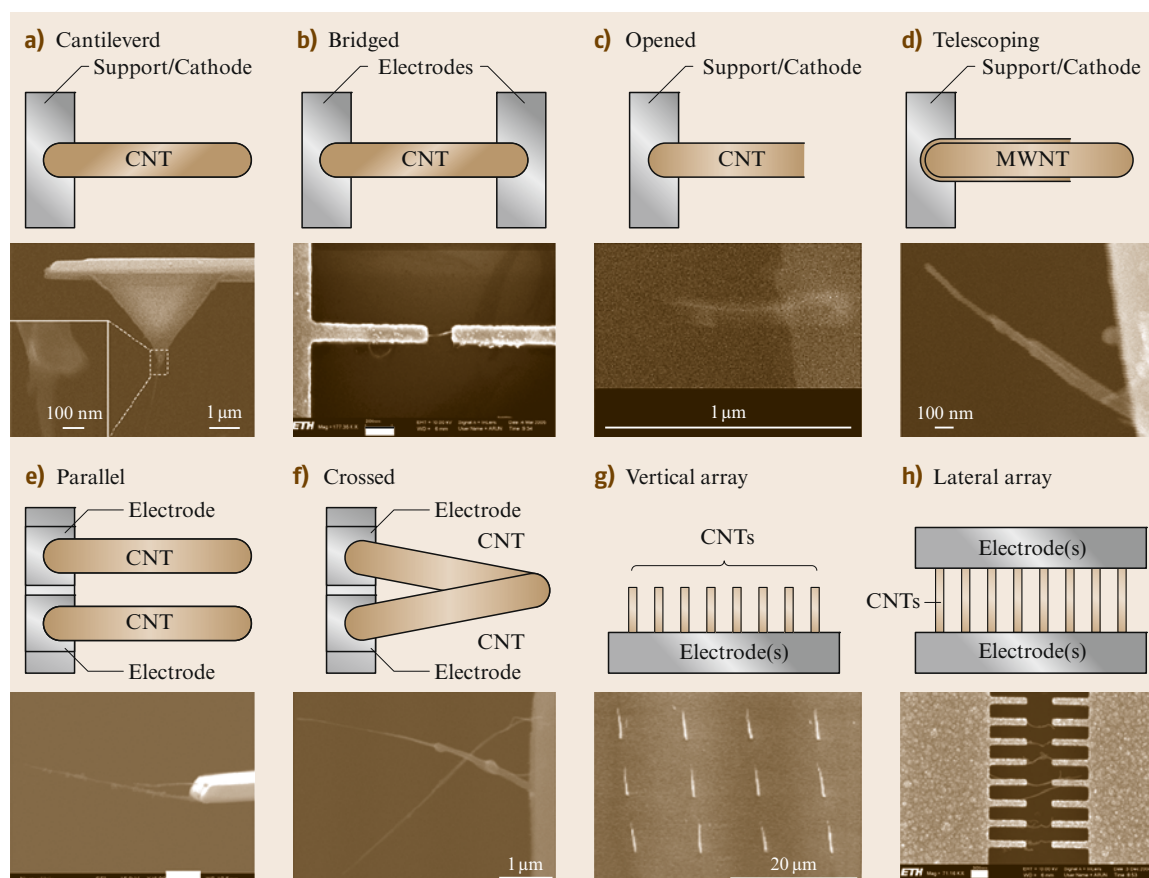

Fig. 27.23a-h Configurations of individual nanotube-based NEMS. Scale bars: (a) 1 μm (inset: 100 nm), (b) 200 nm, (c) 1 μm , (d) 100 nm, (e) and (f) 1 μm , (g) 20 μm , and (h) 300 nm. All examples are from the authors' work

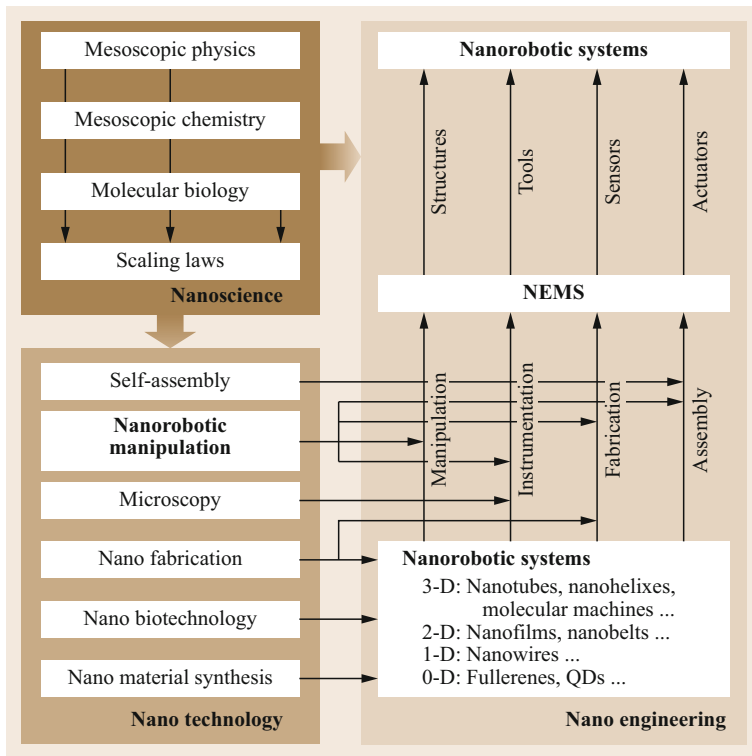

Fig. 27.24 A roadmap for nanorobotic systems

technique can be used to create complex 3-D nanodevices with such building blocks. Nanomaterial science, bio-nanotechnology, and nanoelectronics will also benefit from advances in nanorobotic assembly.

The configurations of nanotools, sensors, and actuators based on individual nanotubes that have been experimentally demonstrated are summarized as shown in Fig. 27.23.

For detecting deep and narrow features on a surface, cantilevered nanotubes (Fig. 27.23a, [27.199]) have been demonstrated as probe tips for an AFM [27.206], a STM, and other types of SPM. Nanotubes provide ultrasmall diameters, ultralarge aspect ratios, and excellent mechanical properties. Manual assembly [27.214], and direct growth [27.215] have proven effective for their construction. Cantilevered nanotubes have also been demonstrated as probes for the measurement of ultrasmall physical quantities, such as femtogram masses [27.170], piconewton-order force sensors, and mass flow sensors [27.197] on the basis of their static deflections or change of resonant frequencies detected within an electron microscope. Deflections cannot be measured from micrographs in real time, which limits the application of this kind of sensor. Interelectrode distance changes cause emission current variation of a nanotube emitter and may serve as

a candidate to replace microscope images. Bridged individual nanotubes (Fig. 27.23b, [27.185]) have been the basis for electric characterization. Opened nanotubes (Fig. 27.23c, [27.216]) can serve as atomic or molecular containers, thermometers [27.217], or spot welders [27.218]. The electrostatic deflection of a nanotube has been used to construct a relay [27.219]. A new family of nanotube actuators can be constructed by taking advantage of the ultralow interlayer friction of a multiwalled nanotubes. Linear bearings based on telescoping nanotubes and a microactuator with a nanotube as a rotation bearing have been demonstrated [27.203, 220], and batch fabrication has been realized based on dielectrophoretically assembled arrays [27.221]. A preliminary experiment on a promising nanotube linear motor with field-emission current serving as position feedback has been shown with nanorobotic manipulation (Fig. 27.23d, [27.216]). Cantilevered dual nanotubes have been demonstrated as nanotweezers [27.222] and nanoscissors (Fig. 27.23e) [27.179] by manual and nanorobotic assembly, respectively. Based on electric resistance change under different temperatures, nanotube thermal probes (Fig. 27.23f) have been demonstrated for measuring the temperature at precise locations. These thermal probes are more advantageous than nanotube-based thermometers because the latter

require TEM imaging. The integration of the aforementioned devices can be realized using the configurations shown in Fig. 27.23g,h [27.183]. The arrays of individual nanotubes can also be used to fabricate nanosensors, such as position encoders [27.223].

Nanorobotic systems remains a rich research field with a large number of open problems. New materials such as nanowires, nanobelts, graphene, and polymer at the nanoscale will enable a new family of sensors and actuators for the detection and actuation of ultra-small quantities or objects with ultrahigh precision and frequencies. Through random spreading, direct growth, optical tweezers, and nanorobotic manipulation, prototypes have been demonstrated. However, for integration into nanosystems, self-assembly processes will become increasingly important. Among them, we believe that dielectrophoretic nanoassembly will play a significant role for large-scale production of regular 2-D structures.

A roadmap for nanorobotic systems [27.224] is shown in Fig. 27.24. Knowledge from mesoscopic physics, mesoscopic/supramolecular chemistry, and molecular biology at the nanometer scale converges to form the field. Various disciplines contribute to nanorobotics, including nanomaterial synthesis, nanobiotechnology, and microscopy for imaging and characterization. Such topics as self-assembly, nanorobotic assembly, and hybrid nanomanufacturing approaches for assembling nano building blocks into structures, tools, sensors, and actuators are considered areas of nanorobotic study. A current focus of nanorobotics is on the fabrication of NEMS and other nanosystems, which may serve as components for future nanorobots. The main goals of nanorobotics are to provide effective tools for the experimental exploration of the nanoworld, and to push the boundaries of this exploration from a robotics research perspective.

27.9 Conclusions

Despite the claims of many *futurists*, such as Issac Asimov's legendary submarine Proteus inside the human body [27.225] and Robert A. Freitas's nanomedical robots [27.226], the form that micro/nanorobots of the future will take and the tasks they will actually perform remain unclear. However, it is clear that technology is progressing towards the construction of intelligent sensors, actuators, and systems on small scales. These will serve as both the tools to be used for fabricating future micro/nanorobots as well

as the components from which these robots may be developed. Shrinking device size to these dimensions presents many fascinating opportunities such as manipulating nano-objects with nanotools, measuring mass in femtogram ranges, sensing forces at piconewton scales, and inducing GHz motion, among other new possibilities waiting to be discovered. These capabilities will, of course, drive the tasks that future micro/nanorobots constructed by and with MEMS/NEMS will perform.

35 Multisensor Data Fusion

Hugh Durrant-Whyte, Sydney, Australia
Thomas C. Henderson, Salt Lake City, USA

Part C covers material related to sensing and perception. The section covers all the aspects of sensing for basic measurement of physical parameters in the world to making sense of such data for the purpose of enabling a robot to perform its tasks. Right now robotics is seeing a revolution in use of sensors. Traditionally robots have been designed to have maximum stiffness and applications have been designed to be predictable in their operation. As robots emerge from the fences areas and we deploy robots for a wider range of applications from collaborative robotics to autonomously driving cars it is essential to have perception capabilities that allow estimation of the state of the robot but also the state the surrounding environment. Due to these new requirements the importance of sensing and perception has increased significantly over the last decade and will without doubt to continue to grow in the future.

The topics addressed in this section include all aspects from detection and processing physical contact with the world through force and tactile sensing over augmented environments for detection of position and motion in the world to image based methods for mapping, detection and control in structured and unstructured environments. In many settings a single sensory modality/sensor is inadequate to give robust estimate of the state of the environment. Consequently a chapter on multi-sensory fusion is also included in this part. Part C considers primarily the sensing and perception aspects of robotics with a limited view to many of the other aspects. Part A is providing the basic, Part B provides the kinematic structures that we need to design control methods for interaction, while Part D will cover the grasping and manipulation of objects. The remaining parts of the handbook covers application verticals where sensors and perception plays a key role.

With this brief overview of Part C, we provide a brief synopsis of each chapter.

Chapter 28 covers force and tactile sensing, which is essential for physical interaction with the world. Tactile sensing addresses the issue of detecting and handling contact with objects and structures in the world. Tactile sensing is essential both for safety and manipulation applications as the control of a robot changes due to contact which changes the kinematic configurations. Force sensing addresses estimation of force and torque as part of dynamic motion but also for interaction with physical objects such as inserting an object or turning a valve. The model chosen for force estimation also impacts the control of the robot.

Chapter 29 covers use of odometry, inertial and **GPS** for estimation of motion and position in the world. Odometry is the ego-estimation of your position/motion

based on robot mounted sensors. With the introduction of sensors for estimation of accelerator and rotational velocity it is possible improve the estimation of position and motion. With the introduction of inexpensive inertial measurement units (**IMU**), driven by the game and phone industry, the use of **IMU** has increased significantly. For outdoor operation it is frequently possible to utilize Global Navigation Systems such as the global positioning systems (**GPS**). The integration of odometry, **IMU** and **GPS** information allow design of systems for precision agriculture, autonomous driving, etc. The chapter provides a description of the core techniques to make this possible.

One of the first sensors to be used for large scale estimation of distance to external objects was sonars. **Chapter 30** covers the basic methods for sound based ranging and localization. Sonars are widely used for underwater mapping and localization, but is also used as an inexpensive modality for localization and ground vehicles and landing of Unmanned Aerial Vehicles. Typically a single sensor has limited precision but through used of phased array techniques and multiple sensors it is possible to achieve high-fidelity ranging. The chapter covers both the basic physics, sensing, and estimation methods.

Over the last two decades we have seen tremendous progress on laser based ranging as a complement to stereo/multi-ocular methods for distance estimation. Light detection and ranging (**LIDAR**) is today used as an effective modality for mapping, localization and tracking of external objects in the environment. In **Chapter 31** the basic techniques for range estimation using light based ranging is described and fundamental methods for three-dimensional (**3-D**) modeling of the environment are described. Recently there has been a renaissance in range based sensing due to the introduction of RGB-D sensors, that utilize structured light and cameras to generate a dense range maps at very-low prices.

Chapter 32 covers the general topics of **3-D** vision which covers estimation of distance from the parallax between two or more cameras and/or the motion of a camera over time. The parallax between two or more images allows estimation of the distance to external objects, which can be leveraged for localization and navigation, but also for grasping and interacting with objects in the environment. The chapter covers both the basic aspects of **3-D** estimation and some of the common applications of **3-D** vision for robot control.

Chapter 33 covers the topic of object recognition. Computer based object recognition has been studied for more than 50 years. Over the last decade we have

seen tremendous progress on object recognition due to improved cameras and availability of much better computers and increased memory. We are seeing both image based recognition techniques and methods for recognition based on the 3-D structure of objects. More recently we have seen a renewed interesting use of neural nets for detection of objects due to new Bayesian methods and the problem of object categorization – recognizing categories of objects such as car, motorcycle, traffic sign, people, etc. has become an important problem. The chapter covers both view and 3-D based methods for recognition and discusses also categorization of objects.

Chapter 34 covers the problem of image servoing. When trying to interact with an object we can use image data to drive the end-effector to a goal location. Two common configurations are eye-in-hand and hand-to-eye. In addition the control can be performed directly in image coordinates or through recovery of two-and-a-half-dimensional (2.5-D) or 3-D pose for an object.

To enable all of this an impact aspect is to derived the relation between changes in robot motion and changes in the image/pose, which is derivation of the Jacobian for the system. This chapter discusses both eye-in-hand and hand-to-eye visual servoing and image/pose based control of the process and provides examples of use of visual servoing in real scenarios.

Finally, the part is concluded by **Chapter 35** which discusses multi-sensory data fusion. As mentioned earlier most applications require use of multiple sensors to generate robust/complete methods for control. Data fusion involves a number of different aspects from time synchronization to transformation into a common reference frame to integration of data over time/space to generate more robust/accurate estimate of the world state. Recently a number of new methods for Bayesian data fusion have emerged. In this chapter the fundamental of data fusion are reviewed and a number of the most common techniques for multi-sensory fusion are introduced.

28. Force and Tactile Sensing

Mark R. Cutkosky, William Provancher

This chapter provides an overview of force and tactile sensing, with the primary emphasis placed on tactile sensing. We begin by presenting some basic considerations in choosing a tactile sensor and then review a wide variety of sensor types, including proximity, kinematic, force, dynamic, contact, skin deflection, thermal, and pressure sensors. We also review various transduction methods, appropriate for each general sensor type. We consider the information that these various types of sensors provide in terms of whether they are most useful for manipulation, surface exploration or being responsive to contacts from external agents.

Concerning the interpretation of tactile information, we describe the general problems and present two short illustrative examples. The first involves intrinsic tactile sensing, i. e., estimating contact locations and forces from force sensors. The second involves contact pressure sensing, i. e., estimating surface normal and shear stress distributions from an array of sensors in an elastic skin. We conclude with a brief discussion of the challenges that remain to be solved in packaging and manufacturing damage-tolerant tactile sensors.

28.1 Overview

Tactile sensing has been a component of robotics for roughly as long as vision. However, in comparison to vision, for which great strides have been made in terms of hardware and software and which is now widely used in industrial and mobile robot applications, tactile sensing always seems to be *a few years away* from widespread utility. So before reviewing the technologies and approaches available, it is worthwhile to ask some basic questions:

- How important is tactile sensing?
- What is it useful for?
- Why does it remain comparatively undeveloped?

In nature, tactile sensing is an essential survival tool. Even the simplest creatures are endowed with large numbers of mechanoreceptors for exploring and responding to various stimuli. In humans, tactile sensing is indispensable for three distinct kinds of activity: ma-

nipulation, exploration and response. The importance of tactile sensing for manipulation is most evident in fine motor tasks. When we are chilled, tasks like buttoning a shirt can become an exercise in frustration. The problem is primarily a lack of sensing; our muscles, snug in our coat sleeves, are only slightly affected but our cutaneous mechanoreceptors are anesthetized and we become clumsy. For exploration, we continually assimilate information about materials and surface properties (e.g., hardness, thermal conductivity, friction, roughness) to help us identify objects. We may have difficulty distinguishing real leather from synthetic leather by sight, but not by touch. Finally, the importance of tactile response, whether to a gentle touch or an impact, is seen in the damage that patients with peripheral neuropathy (e.g., as a complication of diabetes) accidentally do to themselves.

As Fig. 28.1 indicates, the same functional categories apply to robots. However, in comparison to animals, with hundreds or thousands of mechanoreceptors per square centimeter of skin, even the most sophisticated robots are impoverished. One reason for the slow development of tactile sensing technology as compared to vision is that there is no tactile analog to the charge-coupled device (CCD) or complementary metal-oxide semiconductor (CMOS) optical array. Instead, tactile sensors elicit information through physical interaction. They must be incorporated into skin surfaces with compliance, for conforming locally to surfaces, and with adequate friction for handling objects securely. The sensors and skin must also be robust enough to survive repeated impacts and abrasions. And unlike the image plane in a camera, tactile sensors must

	<i>Manipulation:</i> Grasp force control; contact locations and kinematics; stability assessment.
	<i>Exploration:</i> Surface texture, friction and hardness; thermal properties; local features.
	<i>Response:</i> Detection and reaction to contacts from external agents.

Fig. 28.1 Uses of tactile sensing in robotics

be distributed over the robot appendages, with particularly high concentrations in areas like the fingertips. The wiring of tactile sensors is consequently another formidable challenge.

Nonetheless, considerable progress in tactile sensor design and deployment has been made over the last couple of decades. In the following sections we review the main functional classes of tactile sensors and discuss their relative strengths and limitations. Looking ahead, new fabrication techniques offer the possibility of artificial skin materials with integrated sensors and local processing for interpreting sensor signals and communicating over a common bus to reduce wiring.

There is an extensive literature describing touch sensing research. Recent general reviews include [28.1–4] and these cite a number of useful older reviews including [28.5–7].

28.2 Sensor Types

This section outlines five main types of sensors: proprioceptive, kinematic, force, dynamic tactile, and array tactile sensors, as well as sensors that provide thermal or material composition data. However, the emphasis is on sensors that provide mechanoreception, as summarized in Table 28.1. The most important quantities measured with tactile sensors are *shape* and *force*. Each of these may be measured as an average quantity for some part of the robot or as a spatially resolved, distributed quantity across a contact area. In this chapter we follow the convention of studies of the human sense of touch and use the term *touch sensing* to refer to the combination of these two modes. Devices that measure an average or resultant quantity are sometimes referred to as *internal* or *intrinsic* sensors. The basis for these sensors is force sensing, which precedes the discussion of tactile array sensors.

28.2.1 Proprioceptive and Proximity Sensing

Proprioceptive sensing refers to sensors that provide information about the net force or motion of an appendage, analogous to receptors that provide information in humans about tendon tensions or joint movements. Generally speaking, the primary source for spatial proprioceptive information on a robot is provided by joint angle and force–torque sensors. Since joint angle sensors such as potentiometers, encoders, and resolvers are well established technologies, they do not warrant discussion here. Instead, a brief review of proximity sensing via whiskers and antennae as well as noncontact proximity sensing is provided. Force–torque sensors are discussed in greater detail in Sect. 28.2.4.

Table 28.1 Tactile sensor modalities and common transduction types

Sensor modality	Sensor type	Sensor attributes	Advantages	Disadvantages
Normal pressure	Piezoresistive array [28.8–12]	Array of piezoresistive junctions Embedded in a elastomeric skin Cast or screen printed	Suitable for mass production Simple design Simple signal conditioning	Low force thresholds/high sensitivity Frail Signal drift and hysteresis Complex circuitry
	Capacitive array [28.13–17]	Array of capacitive junctions Row and column electrodes separated by elastomeric dielectric	Good sensitivity Moderate hysteresis, depending on construction	
	Piezoresistive microelectromechanical system (MEMS) array [28.18–20]	Silicon micromachined array with doped silicon strain gauged flexures	Suitable for to mass production	Frail
	Optical [28.21, 22]	Combined tracking of optical markers with a constitutive model	No interconnects to break	Requires personal computer (PC) for computing applied forces
Skin deformation	Optical [28.23, 24]	Fluid-filled elastomeric membrane Tracking of optical markers inscribed on membrane coupled with energy minimization algorithm	Compliant membrane No electrical interconnects to be damaged	Complex computations Hard to customize sensor
	Magnetic [28.25]	Array of hall effect sensors		Complex computations Hard to customize sensor
	Resistive tomography [28.26]	Array of conductive rubber traces as electrodes	Robust construction	
	Piezoresistive (curvature) [28.27, 28]	Employs an array of strain gauges	Directly measure curvature	Frailty of electrical interconnects Hysteresis
Dynamic tactile sensing	Piezoelectric (stress rate) [28.19, 29, 30]	polyvinylidene fluoride (PVDF) embedded in elastomeric skin	High bandwidth	Frailty of electrical junctions
	Skin acceleration [28.31, 32]	Commercial accelerometer affixed to robot skin	Simple	No spatially distributed content Sensed vibrations tend to be dominated by structural resonant frequency

Whisker and Antenna Sensors

For many animals whiskers or antennae provide an extremely accurate combination of contact sensing and proprioceptive information. For example, cockroaches can steer themselves along curved walls using only position and rate information from their antennae [28.33]. Other insects and arthropods use numerous small hair sensors on the exoskeleton to localize contacts. Rats perform highly accurate whisking to explore the shapes and textures of objects in their vicinity, with sensor processing performed by a specialized barrel cortex [28.34].

In robotics, this potentially very useful hybrid of proprioceptive and tactile sensing has received comparatively little attention, although examples date at least to the early 1990s [28.35, 36]. In more recent work, *Clements* and *Rahn* [28.37] demonstrated an active whisker with a sweeping motion and *Lee et al.* [28.33] used a passive, flexible antenna to steer a running cockroach-inspired robot. *Prescott et al.* [28.34, 38] have conducted extensive work on active robotic whisking for object exploration and identification, inspired by mammalian models.

Proximity

While proximity sensing does not strictly fall under the category of tactile sensing, a number of researchers have employed proximity sensors for collision detection between a robot arm and the environment; hence, we briefly review these technologies here. Three primary sensor technologies which include capacitive, infrared (IR) optical, and ultrasonic sensors have been used in this application. *Vranish et al.* developed an early capacitive sensor for collision avoidance between the environment and a grounded robot arm [28.39]. Early examples of IR emitter/detector pairs in an artificial skin include [28.40, 41]. A more recent design using optical fibers is reported in [28.42], and an adaptation for a prosthetic hand is reported in [28.43]. Other researchers have developed robot skin that includes ultrasonic and IR optical sensors for collision avoidance [28.44]. *Wegerif* and *Rosinski* provide a comparison of the performance of all 3 of these proximity sensing technologies [28.45]. For a further review of some of these sensors, see Chap. 31 on range sensing.

28.2.2 Other Contact Sensors

There are a variety of other contact-based sensors that are capable of discerning object properties such as electromagnetic characteristics, density (via ultrasound), or chemical composition (cf. animals' senses of taste and smell). While this is beyond the scope of

the current chapter, Chap. 75, on biologically inspired robots, briefly discusses biologically inspired chemical sensors related to smell and taste. For completeness, thermal sensors and material composition sensors are also briefly discussed below.

Thermal Sensors

Thermal sensing is an important element of human tactile sensing, useful for determining the material composition of an object as well as to measure surface temperatures. Since most objects in the environment are at about the same (*room*) temperature, a temperature sensor that contains a heat source can detect the rate at which heat is absorbed by an object. This provides information about the heat capacity of the object and the thermal conductivity of the material from which it is made, making it easy, for example, to distinguish metals from plastics.

Buttazzo et al. [28.46] note that the piezoelectric polymer used in their tactile sensing system is also strongly pyroelectric, and use a superficial layer as a thermal sensor. Other sensors use thermistors as transducers [28.47–49]. Some systems purposely provide an internal temperature reference and use the temperature differential from the environment to detect contacts [28.50, 51]; however, objects with a temperature the same as the reference will not be detected. Most of these sensors have a relatively thick outer skin covering the heat sensitive elements, thus protecting delicate components and providing a conformal surface at the expense of slower response time.

As a more recent example of thermal sensing, *Engel et al.* [28.52] present a flexible tactile sensor design that includes integrated gold film heaters and RTDs (resistance temperature devices) on a polymer micromachined substrate. *Lin et al.* [28.24] include a thermistor as part of the sensing suite in their artificial fingertip. While there is a high level of integration in these sensors, tradeoffs concerning construction, performance, and protection of sensing elements remain an ongoing challenge.

Material Composition Sensors

There has been some work on sensors for material composition. In analogy with the human senses of taste and smell, liquid and vapor phase chemical sensors could potentially determine the chemical composition of a surface [28.53, 54]. However, the large majority of robotic chemical sensing has involved non-contact sensing of airborne plumes [28.55, 56]. Another sensing modality which provides information about material properties is electromagnetic field sensing, using devices such as eddy current or Hall effect probes to measure ferromagnetism or conductivity [28.57, 58].

28.2.3 Kinematic Sensors

Although they are not generally regarded as tactile sensors, sensors that detect the position of a limb can provide the robot with geometric information for manipulation and exploration, particularly when the limb also includes sensors that register contact events. Examples of combining joint angle sensing and contact sensing with compliant fingers to learn about the configuration of a grasp include [28.59, 60].

28.2.4 Force and Load Sensing

Actuator Effort Sensors

For some actuators such as electric servo motors, a measure of the actuator effort can be obtained directly by measuring the motor current (typically using a sensing resistor in series with the motor). However, because motors are typically connected to robot limbs via gearboxes with output/input efficiencies of 60% or less, it is usually much more accurate to measure the torque at the output of the gearbox. Solutions to this problem include torque load cells and mechanical structures at the robot joints whose deflections can be measured using electromagnetic or optical sensors. For cable or tendon-driven arms and hands it is useful to measure the cable tension – both for purposes of compensating for friction in the drive-train and as a way of measuring the loads upon the appendage [28.61, 62]. When fingers or arms make contact with objects in the environment, cable tension sensing becomes an alternative to endpoint load sensing for measuring components of the contact forces. Of course, only those components that produce significant torques can be measured with accuracy. Chapter 19 on multifingered hands contains more details concerning tendon tension measurement.

Force Sensors

When actuator effort sensors are not sufficient to measure the forces exerted by or on a robot appendage, discrete force sensors are typically utilized. These sensors are found most often at the base joint or wrist of a robot but could be distributed throughout the links of a robot.

In principle, any type of multi-axis load cell could be used for manipulator force–torque sensing. However, the need for small, lightweight units with good static response eliminates many commercial sensors. The design of force sensors for mounting above the gripper at the wrist has received the most attention [28.63, 64], but fingertip sensors for dextrous hands have also been devised. Often these sensors are based on strain gauges mounted on a metal flexure [28.65–67] which can be fairly stiff and robust. *Sinden* and *Boie* [28.68] propose a planar six axis force–torque

sensor based on capacitive measurements with an elastomer dielectric. Design considerations for force sensors include stiffness, hysteresis, calibration, amplification, robustness, and mounting. *Dario* et al. present an integrated fingertip for robotic hands integrated FSR (force sensing resistor) pressure array, piezoceramic bimorph dynamic sensor, and force–torque sensor [28.29]. More recently *Edin* et al. [28.69] have developed a miniature multi-axis fingertip force sensor (Fig. 28.2). For applications where immunity to electromagnetic noise is desirable, *Park* et al. [28.70] present a robot fingertip with embedded fiber optic Bragg gratings, used as optical strain gages. *Bicchi* [28.71] and *Uchiyama* et al. [28.72] consider the optimal design of multi-axis force sensors in general.

Information from the force sensors can also be combined with knowledge of fingertip geometry to estimate contact location, as implied in Fig. 28.3. This method of contact sensing is referred to as *intrinsic tactile sensing* and was first presented by *Bicchi* et al. [28.73]. A comparison between intrinsic and extrinsic contact sensing

Fig. 28.2 Miniature fingertip force–torque sensor for a prosthetic hand (after [28.69])

Fig. 28.3 Robot hand with fingertip force and tactile sensing. Information from the force sensors can be combined with knowledge of fingertip geometry to estimate contact location, referred to as *intrinsic tactile sensing*

(i.e., using distributed contact sensors) is presented by Son et al. [28.74]. This topic is discussed further in Sect. 28.3.1.

28.2.5 Dynamic Tactile Sensors

Taking a cue from the role of fast-acting or dynamic tactile sensors in human manipulation [28.75], researchers have developed dynamic sensors for slip detection and for sensing textures and fine features.

Early slip sensors based on displacement detected the motion of a moving element such as a roller or needle in the gripper surface [28.76, 77]. Subsequent work has typically used accelerometers or other sensors that are inherently sensitive to small, transient forces or motions. Early examples include [28.31, 78–80]. Many subsequent contributions are reviewed in [28.81].

For the case of hard objects held in metal grippers, acoustic emissions may reveal slip [28.82]. Because these signals are at very high frequency (over 100 kHz) they can be useful for distinguishing among different kinds of contact events in noisy environments [28.83]. Another approach for improving the signal/noise robustness of dynamic sensing is to use an actively stimulated sensor and measure the change in response as contact conditions change [28.84, 85].

For grasp force control, it is especially useful to detect incipient slips, which are accompanied by small, localized vibrations, or micro-slips, at the periphery of a finger/object contact region before gross sliding occurs. The challenge is to distinguish these from other events that produce vibrations [28.86–89].

For detecting features and fine surface features it can be effective to use small fibers, a skin with fingerprint-like ridges, or a stylus that drags over the surface like a fingernail [28.46, 90, 91].

Because many dynamic tactile sensors only produce a transient response, they are often combined with pressure sensing arrays or force sensors to provide a combination of low frequency and high frequency tactile sensing [28.24, 29, 32, 46, 89, 92, 93]. An alternative, which can be simpler from the standpoint of sensor integration, is to use conventional pressure sensing arrays for slip detection. In this case, the array resolution and scanning rate must be sufficient to detect motion or incipient motion quickly, to prevent grasp failures. Fortunately, this is becoming increasingly feasible [28.19, 81, 94, 95].  VIDEO 14 shows an example of dynamic tactile sensing.

28.2.6 Array Sensors

Hundreds of designs for tactile array sensors have appeared in the literature in the last 25 years, and many

of them are designed for use with dextrous hands. In terms of transducers, the fundamental requirement is to unambiguously recover either the shape or pressure distribution across the contact. Shape sensing requires a compliant skin, which can also have advantages for grasp stability (see Chaps. 37 and 38 on contact modeling and grasping). Examples of shape-sensing tactile arrays include [28.23, 24]. However, the far more common approach is to measure subsurface strains, which can be correlated with surface pressure distributions, as presented by Fearing and Hollerbach [28.96] and discussed further in Sect. 28.3.2.

Contact Location Sensors

The simplest and perhaps most robust tactile arrays provide measurements solely of contact location. Some such sensors utilize a membrane switch design like that found in keyboards [28.97]. As another example, a robust two-dimensional (2-D) switch array can be embedded in a prosthetic hand [28.69]. Some optical tactile sensors have also been used primarily as contact location sensors. Maekawa et al. [28.98] used a single optical position sensing device (PSD) or a CCD camera array to detect the position of scattered light off of a hemispherical optical wave guide fingertip with a silicone rubber cover. Light is scattered at the locations of contacts. With a textured skin, the magnitude of the force can also be estimated, as the contact area grows in proportion to the pressure. However, an issue with fingertips that use a compliant skin covering a hard substrate is that adhesion between the two materials results in hysteresis. In addition, when the fingertip is dragged over a surface, the friction can produce a shift in the estimated contact position.

Pressure Sensing Arrays

Capacitive Pressure Sensing Arrays. Capacitive pressure sensing arrays are one of the oldest and most common tactile sensor types. Some of the earliest analysis of such sensors is presented by Fearing [28.99] for capacitive arrays embedded into a soft robot fingertip. The arrays consist of overlapping row and column electrodes separated by an elastomeric dielectric, forming an array of capacitors. A change in capacitance results from compressing the dielectric between row-column plates at a particular intersection. The equation for capacitance, based on the physical parameters, is expressed as $C \approx \epsilon A/d$, where ϵ is the permittivity of the dielectric between the plates of the capacitor, A is the area of the plates, and d is the spacing between them. Pressing on the skin reduces the plate spacing d , thus providing a linear response with displacement. Through appropriate switching circuitry, a region of a sensor array can be isolated at a particular

row/column intersection. Examples of similar capacitive tactile arrays can be found in [28.100, 101] and commercially [28.14]. Large capacitive arrays have also been developed to cover the arms of a robot [28.15–17]. A woven fabric with capacitive sensing junctions is reported in [28.102].

With a suitable dielectric and plate design, capacitive arrays can be robust, have a large dynamic range (ratio between minimum and maximum detectable pressure) and low hysteresis, which is desirable for fast response. However, a common problem is the need to shield the array from stray capacitance effects (e.g., from an approaching metallic surface) and to minimize *parasitic* capacitance associated with wiring to and from the active elements. For these reasons, the recent trend is to use local microprocessors specialized for capacitance measurement as part of an integrated sensing system (Sect. 28.4). An example is shown in Fig. 28.4.  VIDEO 15 actually shows results taken with the sensor depicted in Fig. 28.4.

Piezoresistive Pressure Sensing Arrays. Many researchers have produced tactile sensor arrays that are piezoresistive. In most cases, these sensors utilize a conductive rubber that is bulk molded or a piezoresistive ink that is patterned via screen printing or stamping. Each of these approaches employs a conductive additive (typically carbon black or silver) to create its conductive/piezoresistive behavior. As a more flexible and durable alternative, some researchers have developed fabric-based piezoresistive sensors, discussed separately below.

Russell [28.27] presented one of the first molded conductive rubber tactile sensor arrays composed of

Fig. 28.4 Capacitive touch and joint angle sensors on a flexible circuit for incorporation in a robotic hand, sharing the same microprocessors for signal processing and communication (after [28.103])

conductive rubber column and row electrodes with piezoresistive junctions. However, this sensor exhibited significant drift and hysteresis, which fueled research to minimize these effects through proper selection of molding material [28.8]. These issues were never completely solved due to the hysteretic nature of elastomers, but this sensing approach remains attractive due to its ease of manufacturing. Hence, it has continued to find applications, for example, in the appendages of humanoid robots where extreme accuracy is not required [28.104]. Significant improvements in dynamic range and robustness are also possible using a treated elastomer that exploits a quantum tunneling effect [28.105], and commercial versions are now available [28.106].

A number of researchers and companies have developed tactile sensors that utilize conductive (piezoresistive) ink, generally referred to as **FSRs** (force sensitive resistors). This is by far the most common and economical means to incorporate tactile sensing via off-the-shelf sensors. However, to make highly integrated, dense sensor arrays, custom fabrication is necessary. Examples of such sensors include [28.9, 29]. To take this basic concept a step further, *Someya* [28.107] has produced robotic skin that employs patterned organic semiconductors for local amplification of the piezoresistive sensor array, printed on flexible polyimide film. Although fabricated on a flexible substrate, these sensor arrays are somewhat susceptible to bending fatigue.

Piezoresistive fabrics have been developed to address fatigue and fragility issues found in tactile arrays. Examples of these sensors are presented in [28.10–12, 108] and are utilized in applications such as the arms or legs of humanoid robots. Because this technology has the potential to replace ordinary cloth, it is a promising technology for applications in wearable computing or even smart clothing. A different solution to the problem of making a sensor that will work on joints and locations with extensive flexing is to employ fine channels of liquid metal in a stretchy elastomer [28.109].

One final design that does not fall under the above fabrication categories is a sensor designed by *Kageyama et al.* [28.110] that utilizes a piezoresistive conductive gel pressure array along with a multi-level contact switch array via variable contact resistance within sensor layers that they developed for use in humanoid robots.

MEMS arrays. **MEMS** technology is attractive for producing dense sensor arrays with integrated packaging, signal processing and communications electronics. Early devices were produced in silicon through standard silicon micro-machining techniques, allowing high spatial resolution and dedicated hardware for multi-

plexing, etc. [28.111, 112]. However, such silicon-only devices can be brittle and difficult to integrate into a robust, compliant skin. More recent efforts have addressed these problems by using combinations of semiconductors and other materials, including organic semiconductors [28.18, 19, 52, 113, 114].

Returning to the idea of using silicon load cells for tactile sensing, *Valdastri et al.* [28.115] developed a miniature MEMS silicon-based three-axis load cell that resembles a joystick and is appropriate for embedding within an elastomeric skin for detecting shear and normal stresses (Fig. 28.5) [28.93]. Other recent efforts include flexible arrays with high spatial resolution using capacitive or piezoresistive technology [28.20, 116].

Skin Deflection Sensing

Brocket [28.117] was one of the first to propose the idea of using deformable membranes as robot fingertips. As noted by *Shimoga and Goldenberg* [28.118], there are several advantages to using deformable fingertips over more rigid robot fingertips, which include: 1) improved grasp stability, 2) reduced shock, and 3) reduced fatigue for embedded sensor elements. Other early work includes a deformable fingertip with skin covering polyurethane foam and instrumented with elastomeric strain gauges [28.27].

Nowlin [28.25] used Bayesian algorithms to improve data interpretation of a deformable tactile sensor that used magnetic field sensing. A 4×4 array of magnets were supported above paired hall-effect

sensors off a rigid base by individual fluid filled balloons. Hall-effect sensors measure the strength of the local magnetic field, which should increase with proximity to the magnets; however, this is complicated by neighboring magnets in the array. Hence, noisy data were combined using Bayesian algorithms to predict membrane deformation for a deformable fingertip.

Later, *Russell and Parkinson* [28.26] developed an impedance tomographic tactile sensor, capable of measure skin deformation over an 8×5 array. This sensor was constructed with of neoprene rubber and filled with distilled water, similar to the more recent BioTac sensor [28.24]. Row and column electrodes were made from copper and conductive rubber for the rigid substrate and neoprene skin, respectively. Like the capacitive tactile sensors described above, this sensor utilized multiplexing electronics to reduce the number of electrical interconnects. Square waveform driver electronics are used to estimate the resistance of a column of water formed between row and column elements providing a signal that is proportional to the current skin height.

Ferrier and Brocket [28.23] implemented a tactile sensor which used optical tracking in combination with models of the skin to predict sensor fingertip deformations. The fingertip sensor consists of a tiny CCD camera focused on a 7×7 array of dots marked on the inside of a gel-filled silicone membrane. An algorithm is used to construct a 13×13 grid over the array of dots. This algorithm uses a combination of the position that is sensed by the CCD camera, which provides the location along a line radially outward from the focal point, in combination with a mechanical model used to solve for the radial distance from the camera focal point, based on energy minimization.

A more recent example of a shape sensing array is the commercial Syntouch BioTac that grew out of research on a multimodal fingertip tactile sensor [28.24]. In this design, measuring the changes in resistance between terminals in a water-filled skin provides an estimate of the skin deformation.

Other Array Tactile Array Sensors

While less common than capacitive or piezoresistive sensors, optical tactile sensors have consistently been attractive for their immunity to electromagnetic interference. The basic approaches include designs that use a small camera to measure skin deformations and arrays of optical emitters and detectors. Optical fibers can also be used to separate the transducer from the contact site [28.42, 119].

An interesting tactile sensor uses vision to track an array of spherical markers embedded in a transparent elastomer to infer the stress state of the skin material

Fig. 28.5 (a) Scanning electron microscope (SEM) micrographs of a MEMS 3-axis tactile force sensor. (b) MEMS force sensor wirebonded to a flex-circuit and embedded within a silicone rubber skin (after [28.115])

due to applied forces [28.21]. This sensor is currently being commercialized under the tradename GelForce.

Miniaturization of optical components has also made it possible to construct a tactile array of surface-mounted optical devices. In a physically robust design that can be adapted for shear and normal sensing, emitters and detector pairs are covered by a thin translucent layer of silicone rubber followed by an opaque outer layer. As the silicone skin is depressed, there is a variation in the amount of light reflected from the emitter to the detector [28.22, 120].

The concept of reflection off the underside of a compliant skin has also been used with acoustic or ultrasonic sensors. *Shinoda* et al. [28.121] present a sensor that looks at the change in reflected acoustic energy from a resonator chamber near the surface of the

skin, with application to friction measurement [28.122]. *Ando* et al. [28.123] present a more sophisticated ultrasound sensor that achieves 6-DOF (degree of freedom) displacement sensing via paired plate elements that utilize 4 ultrasound transducers per plate.

Multimodal Arrays

Human sensing is inherently multi-modal, with combinations of fast- and slow-acting mechanoreceptors as well as specialized thermal and pain receptors. In an analogous approach, a number of researchers have developed multi-modal tactile sensing suites that combine mechanical and thermal sensing [28.24, 49, 52, 124, 125]. As noted earlier, other work has combined static and dynamic sensing [28.24, 29, 32, 46, 92, 93, 126].

28.3 Tactile Information Processing

In discussing the processing of tactile information, we return first to the three main uses depicted in Fig. 28.1. For manipulation, we require, foremost, information about contact locations and forces so that we can grasp objects securely and impart desired forces and motions to them. For exploration, we are concerned with obtaining and integrating information about the object, including the local geometry, hardness, friction, texture, thermal conductivity, etc. For response, we are concerned especially with the detection of events, such as contacts produced by an external agent, and in assessing their types and magnitudes. The uses of information are often coupled. For example, we manipulate objects in order to explore them, and we use the information obtained through object exploration to improve our ability to control forces and motions in manipulation. Recognizing contact events is also important for manipulation and exploration, as it is for response.

28.3.1 Tactile Information Flow: Means and Ends of Tactile Sensing

Figure 28.6 summarizes the general flow of information from each type of sensor reviewed in the previous section through primary sensed quantities to information provided for manipulation, exploration and response. A useful thought exercise is to consider exactly what information we use to perform a task such as turning a pen end-over-end between the fingers. We can easily perform this task with our eyes closed. What information are we using? We need to track the position and orientation of the pen and to monitor the forces that we impose on it to maintain stable manipulation. In other words,

we need to know the *configuration* of our grasp, the *locations and movements of contacts* over the surfaces of our fingers, the *magnitudes of grasp forces* and the *contact conditions* with respect to friction limits, etc. The same requirements apply for robots and are provided by the information flow in Fig. 28.6.

At the upper left corner of the figure, joint angles, combined with the forward kinematic model of the manipulator and knowledge of external link geometries, establish the positions and orientations of coordinate frames embedded in the fingertips. This information is needed to integrate local information about object shape, surface normal orientation, etc. so that the overall geometry and pose of the object can be determined.

Actuator effort sensors provide information about the resultant forces, using the Jacobian transpose: $\mathbf{J}^T \mathbf{f} = \boldsymbol{\tau}$, where \mathbf{f} is an $n \times 1$ vector of external forces and moments taken with respect to a coordinate frame embedded in the appendage. \mathbf{J}^T is the Jacobian transpose, mapping external forces and moments to joint torques, and $\boldsymbol{\tau}$ is an $m \times 1$ vector of joint torques for a serial kinematic chain with m degrees of freedom. We require that the k -th column of \mathbf{J}^T have elements that are relatively large compared to the overall condition number of \mathbf{J} to provide an accurate measurement of the k -th element of \mathbf{f} . *Eberman* and *Salisbury* [28.127] show that it is possible to measure contact force and location using only joint torque measurements if the manipulator has clean dynamics.

Alternatively, we can use a multi-axis force–torque sensor in the fingers, as shown in Fig. 28.3, or robot wrist to obtain contact forces. This approach has the advantage of providing dynamic force signals with

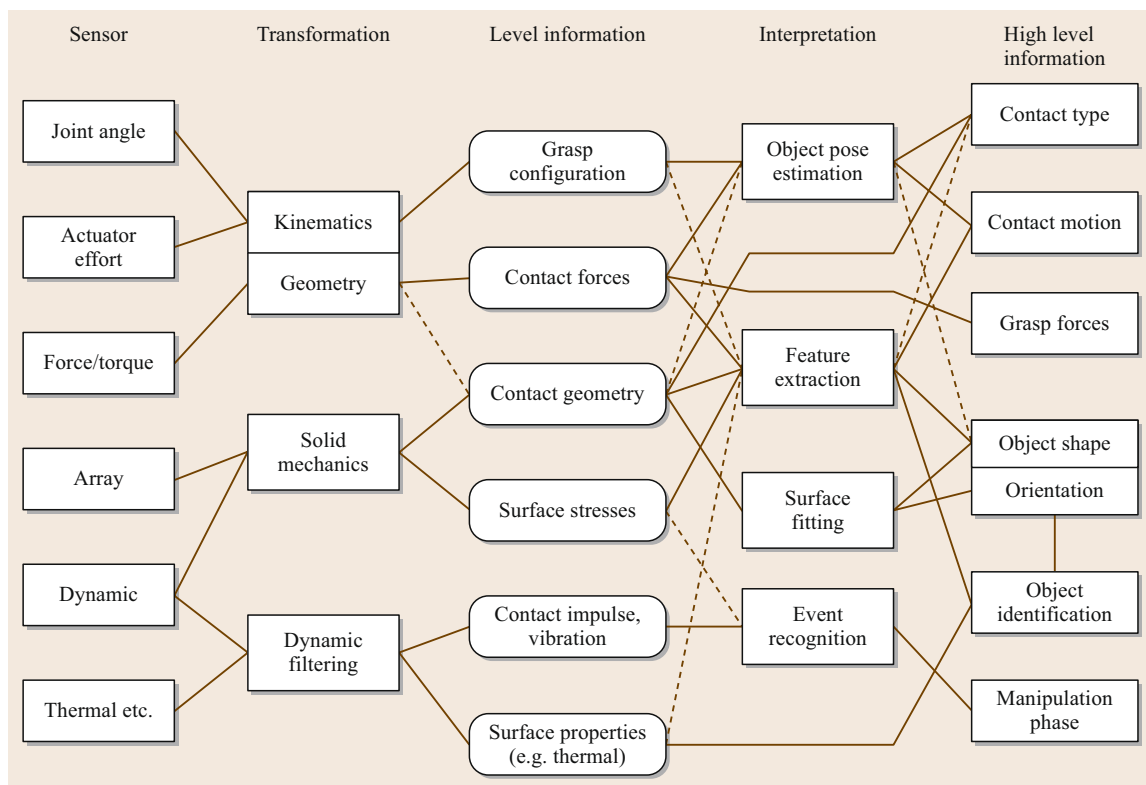

Fig. 28.6 Force and tactile sensor information flow and signal processing

a higher signal/noise ratio because they are not masked by the inertias of the robot arm or fingers and their transmissions. If the geometry of the fingertip is known, one can use *intrinsic tactile sensing* [28.65, 128] to compute the contact location as well as the contact force by examining ratios of resultant forces and torques at the sensor.

When the contacts are small compared to the fingertips (so that a point-contact approximation applies) and the fingertips are convex shapes, the contact location is easily computed. Fig. 28.7 shows a contact force \mathbf{f} , contacting the fingertip surface at a location \mathbf{r} . A force-torque sensor such as that in Fig. 28.2 measures the moment, $\boldsymbol{\tau} = \mathbf{r} \times \mathbf{f}$, with respect to the origin. If we consider the lever arm \mathbf{h} , perpendicular to the line of action of \mathbf{f} , then $\mathbf{h}/h = \mathbf{f}/f \times \boldsymbol{\tau}/\tau$, where $h = \tau/f$ is the magnitude of \mathbf{h} . We can then write that $\mathbf{r} = \mathbf{h} - \alpha\mathbf{f}$, where α is a constant obtained by solving for the intersection of the line of action and the fingertip surface. For a convex fingertip, there will be two such points, of which only one corresponds to a positive (inward) contact force.

From the contact location one can deduce the local contact normal and contact kinematic type from a small number of force measurements. *Bicchi* presents algorithms for extending these methods to soft fin-

gers [28.128]. *Brock* and *Chiu* [28.66] describe the use of force sensors for the perception of object shape using this approach and for measuring the mass and center of mass of a grasped object.

For precision tasks involving small objects or small forces and motions, cutaneous sensors provide the most sensitive measurements. In general, as task require-

Fig. 28.7 Intrinsic tactile sensing: a contact produces a unique line of action and moment about the origin of a coordinate system in the fingertip. The contact location can be obtained by solving for the intersection of the line of action and the fingertip surface

ments get smaller, the sensor must be located closer to the contact so that the compliance and inertia of the intervening parts of the manipulator do not interfere with the measurement. *Dario* [28.129] suggests that finger tip force sensors are useful for forces of 0.1–10.0 N while array sensors can measure distributed forces of 0.01–1.0 N. *Son et al.* [28.74] find that intrinsic tactile sensing and array sensors can both provide accurate (within 1 mm) estimates of contact location; however, the intrinsic tactile sensing method is inherently sensitive to the accuracy of the force–torque sensor calibration and can produce transient errors due to unmodeled dynamic forces.

Proceeding down the left side of Fig. 28.6 we come to the large category of cutaneous array sensors. The interpretation of information from array sensors depends initially on the transducer type. For arrays of binary contact or proximity sensors, interpretation amounts mainly to establishing the location and general shape of the contact area. Techniques common to binary vision can be used to obtain sub-pixel resolution and to identify contact features. This information, in combination with measurements of the grasp forces from actuator effort or force–torque sensors, is sufficient for basic manipulation tasks [28.69].

28.3.2 Solid Mechanics and Deconvolution

A basic problem associated with tactile array sensors is to reconstruct what is happening at the surface of the skin from a finite set of measurements obtained beneath the surface. Typically we are interested in determining pressure and perhaps shear stress distributions associated with contacts on the skin. In other cases, as when the fingertips consist of a gel or soft foam covered by a thin membrane so that the pressure is nearly constant, the local geometry of the contact is of interest.

In the following example we consider the case of an array of elements located at a depth d below the surface of an elastomeric skin. A contact has resulted in a pressure distribution over the region of interest. We establish a coordinate system with z pointing in the inward normal direction and, for simplicity, we examine a one-dimensional loading case, $p(y)$, in which the pressure distribution is unchanging in the x direction. We further assume that the extent of the skin in the x direction is large compared to the skin thickness so that strains in the x direction are inhibited, leading to a plane strain elasticity problem. We assume that the skin is a homogenous, isotropic material and the strains are small enough that linear elasticity theory can be applied. Of course, none of these assumptions is entirely valid in practical cases; however, the results do agree qualitatively with the measurements obtained

with actual robot fingers and tactile arrays. A thorough discussion of the general approach and of the accuracy of the linear elastic models can be found in [28.91, 96, 99, 130, 131].

Figure 28.8 illustrates the case of two line loads, or knife edges, pressed against the surface of the skin (akin to a planar version of the two-point discrimination test for human tactile acuity). The solution for a single line load, or impulse response, was derived by Boussinesq in 1885. For the case of plane strain the principal stresses in the (y, z) plane from a normal unit impulse can be expressed in cartesian coordinates as [28.132]

$$\sigma_z(y, z) = \left(\frac{-2}{\pi z} \right) \frac{1}{[1 + (y/z)^2]^2}, \quad (28.1)$$

$$\sigma_y(y, z) = \left(\frac{-2}{\pi z} \right) \frac{(y/z)^2}{[1 + (y/z)^2]^2}, \quad (28.2)$$

$$\sigma_x(y, z) = \nu(\sigma_y + \sigma_z), \quad (28.3)$$

where ν is Poisson's ratio for the material (typically 0.5 for elastomeric materials).

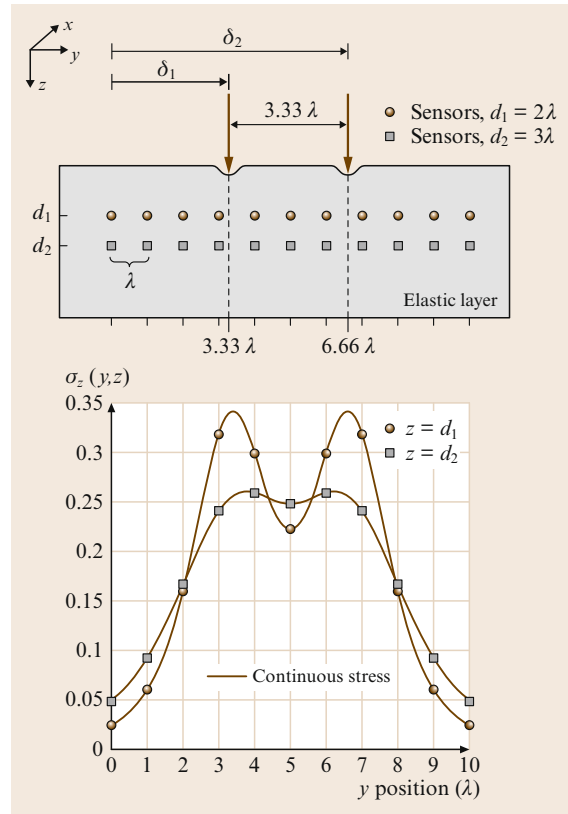

Fig. 28.8 Plane strain stress response for two (unit magnitude) line loads. Note the *blurring* that occurs with greater depth

For two such line loads located at distances δ_1 and δ_2 from the origin, the solution can be obtained by superposition

$$\sigma_z(y, z) = \left(\frac{-2}{\pi z} \right) \left\{ \frac{1}{\left[1 + \left(\frac{y - \delta_1}{z} \right)^2 \right]^2} + \frac{1}{\left[1 + \left(\frac{y - \delta_2}{z} \right)^2 \right]^2} \right\}, \quad (28.4)$$

$$\sigma_y(y, z) = \left(\frac{-2}{\pi z} \right) \left\{ \frac{\left(\frac{y - \delta_1}{z} \right)^2}{\left[1 + \left(\frac{y - \delta_1}{z} \right)^2 \right]^2} + \frac{\left(\frac{y - \delta_2}{z} \right)^2}{\left[1 + \left(\frac{y - \delta_2}{z} \right)^2 \right]^2} \right\}. \quad (28.5)$$

For more general pressure distributions the stresses can be found by convolution of the pressure distribution, $p(y)$, and the impulse response $G_i(y, z)$

$$\sigma_i = \int_{\tau=-\infty}^{\tau=y} [p(\tau) d\tau] G_i(y - \tau, z). \quad (28.6)$$

Also plotted in Fig. 28.8 are curves corresponding to the vertical stress components, σ_z , at two different depths $d_1 = 2\lambda$ and $d_2 = 3\lambda$, where λ is the sensor spacing. As we go deeper beneath the skin, the stresses become smoothed or blurred, and the ability to distinguish between closely spaced impulses diminishes. However, the blurring of concentrated pressure distributions can also provide an advantage when we have a limited number of sensors because the stresses and strains spread over a larger area and are more likely to affect at least one sensor. The elastic skin also provides a kind of automatic *edge enhancement* because stresses are high at the transitions between loaded and unloaded regions of the skin.

In most cases, for example in the case of capacitive or magnetic sensors, the sensing elements will measure strains or local deformations of the skin material in the vertical direction. In a few cases, such as pieces of piezoelectric film embedded in an elastomeric skin [28.91], the sensors are sufficiently stiff compared to the surrounding material that they can be considered to measure stresses directly.

For the case of elastic plane strain, the strains are related to the stresses by [28.133]

$$\epsilon_y = \frac{1}{E} [\sigma_y - \nu(\sigma_x + \sigma_z)], \quad (28.7)$$

$$\epsilon_z = \frac{1}{E} [\sigma_z - \nu(\sigma_x + \sigma_y)], \quad (28.8)$$

where E is the Young's modulus and ν is the Poisson's ratio, which we assume is 0.5 for an elastomeric skin.

Figure 28.9 shows the typical measurements that may be obtained from a row of sensing elements from the two line loads applied in Fig. 28.8. Each bar corresponds to the strain, ϵ_{zi} measured by a corresponding element and computed using (28.8), with stresses obtained from (28.3)–(28.5).

The problem at this point is to produce a best estimate of the surface pressure distribution, $p(y)$, from this finite set of subsurface strain measurements. The problem is a classic example of estimating a signal from a sparse set of remote measurements. One approach to this process is based on deconvolution techniques [28.91, 96, 99]. The measured signal from the sensors ϵ_z is convolved with the inverse of the impulse strain response $H(y)$ to find an estimate of the surface pressure that produced the signals. The inversion tends to amplify high frequency noise, and the inverse filter bandwidth must be limited according to the spatial density of the sensors and their depth below surface.

Another approach [28.21, 130] is to assume that the surface pressure distribution can be approximated by a finite set of impulses $\mathbf{p} = [p_1, p_2 \dots p_n]^T$. The sensor readings form a vector, $\boldsymbol{\epsilon} = [\epsilon_1, \epsilon_2 \dots \epsilon_m]^T$, where $m > n$ for the bandwidth limitations discussed above. The strain response can then be written as a matrix

Fig. 28.9 Measured strain with assumed 10% noise

equation

$$\epsilon = \mathbf{H}p. \quad (28.9)$$

Each element of \mathbf{H} is computed using (28.8) with σ_z and σ_y computed using equations similar to (28.4) and (28.5) and with σ_x from (28.3). The estimated discrete pressure distribution is then found by taking the pseudoinverse of \mathbf{H}

$$\hat{p} = \mathbf{H}^+ \epsilon. \quad (28.10)$$

Using the strain measurements from Fig. 28.9, at a depth $d = 2\lambda$, the estimated pressure distribution using the pseudoinverse method is seen in Fig. 28.10. In this example, because the assumed set of seven impulses matches fortuitously with the actual loading, the reconstruction is fairly accurate despite the assumed noise.

An alternative approach to constructing soft robot finger tips is to enclose a compliant medium such as foam rubber or fluid in a thin elastic membrane [28.25, 27, 117, 134–137]. Some of the tactile array sensors developed for these fingers are able to measure directly the shape of the membrane, so that a physical model is not needed for interpretation of the signal [28.25]. Another sensing scheme uses an array of magnetic sensors at the center of the finger to measure the changes in the magnetic field generated by deformations of the magnet-loaded membrane [28.137]. A statistical algorithm has been developed that can robustly determine the membrane shape from the sensor signals [28.25]. However, a mechanical model is still required to find the pressure distribution across the contact from the shape information provided by all of these sensors.

Fig. 28.10 Estimated surface pressure distribution using pseudoinverse method for 11 sensors and 7 assumed impulses

28.3.3 Curvature and Shape Information

Another alternative to measuring subsurface strains or deflections is to measure directly the local curvature at each element of an array of sensors. The curvature information can be applied directly toward identifying contact type and centroid location or integrated to obtain the local shape of the contact [28.28, 138].

Returning to Fig. 28.6, once the local contact shape or geometry has been established, the next steps typically include feature identification (e.g., identifying corners or ridges on an object) and determining the overall shape and pose of the object in the hand.

Often the object shape is at least partially known a priori in which case a variety of surface or data fitting methods can be used. For example, *Fearing* [28.139] developed a method for calculation of the radius of curvature and orientation of a generalized cylinders from tactile array data and [28.140] developed a neural network that performs a similar calculation. Other schemes use contact locations, surface normals and contact forces to determine information about object shape and orientation with respect to the hand [28.141–144].

Allen [28.145] uses several different primitive representations for object shape attributes based on the particular exploratory procedure used to sense the object. Object volume and approximate shape are perceived with enclosure grasping, and the resulting shape is modeled using superquadric surfaces. Similarly, measurement of the lateral extent of object faces leads to a face-edge-vertex model and contour following to a generalized cylinder representation.

The question of what constitutes an appropriate set of features is not well understood, although it clearly depends on the intended application. *Ellis* [28.146] considers appropriate feature sets and methodologies for acquiring the needed data. *Lederman* and *Browse* [28.147] suggest that surface roughness, surface curvature, and oriented edges are used in human haptic perception.

28.3.4 Object and Surface Identification

The most common application of touch information has been in object recognition and classification. In object recognition the goal is to identify one object from a set of known objects using information derived from touch. In classification the goal is to categorize objects according to preselected sensed properties. These systems are usually based on geometric information derived

from tactile array or force sensors, although some approaches use additional information (e.g., compliance, texture, thermal properties and the kinematic pose of the hand) [28.148–154].

28.3.5 Active Sensing Strategies

Because touch provides only local information, movement is an integral part of touch sensing for recognition and exploration. A review of tactile sensing focusing on exploration and manipulation is found in [28.2]. Several researchers have developed strategies for scheduling sensor movements so that each additional observation decreases the number of objects which are consistent with prior observations. This is sometimes described as a *hypothesize and test* approach. Early examples include [28.141, 155–157].

Klatzky et al. [28.149] have suggested that robotics systems can employ the same exploratory procedures used by humans in haptic exploration. These procedures prescribe the finger motions needed for tasks such as tracing object contours, measuring compliance, and determining the lateral extent of object surfaces. Early work on exploratory tactile sensing includes [28.145, 158, 159]. More recent examples include [28.32, 160, 161].

Edge tracking and surface following strategies have received particular attention. Early examples include [28.162–166]; a more recent example is found in [28.167].

28.4 Integration Challenges

A critical problem that we have not yet addressed is the difficulty of connecting to a large and diverse array of tactile sensors. In 1987 Jacobsen et al. [28.172] cited the routing of wires as perhaps the most difficult problem in dexterous hand design and, to a large extent, this remains true today. However, some solutions to this problem have been presented in recent years using wireless sensor arrays or digital busses for power and signal connections.

In early work, Shinoda and Oasa [28.173] embedded tiny wireless sensing elements in an elastic skin that uses an inductive base coil to provide power and signal transmission. Hakozaiki and Shinoda [28.174] embed tactile sensor chips between 2 layers of conductive rubber provide power and serial communication. In other work, [28.18, 20] produce large scale printed arrays with built-in multiplexing and communications.

28.3.6 Dynamic Sensing and Event Detection

For dynamic tactile sensors used to detect such events as gentle contacts or slippage between the fingertips and an object, the main challenge is to reliably detect the event in question without false positives. The dynamic tactile sensors that produce large signals in response to contact events are also prone to producing large signals in response to vibrations from the robot drive train and to rapid accelerations of the robot hand. Solutions for more robustly detecting contact events include comparing the signals from dynamic tactile sensors at and away from the contact regions and statistical pattern recognition methods to identify the *signature* of true contact events. Early examples include [28.86, 127, 168]. More recent examples have taken advantage of the much greater realtime processing capability that is now available for signal processing and event classification [28.32, 161, 169, 170].

28.3.7 Integration of Thermal and Other Sensors

Sensors such as thermal contact sensors are rarely used in isolation; their signals are generally integrated with those from tactile arrays and other sensors to produce additional information for identifying objects. Examples of integrated thermal and mechanical sensors for surface characterization include [28.24, 52, 171].

In a different approach, Yamada et al. [28.168] use wireless sensor chips and light transmitted through a transparent elastomer both for power and to communicate to a power-receiver chip. Ascari et al. [28.175] propose a communications scheme with all information transmitted along optical fibers.

In recent years, the proliferation of microprocessors that can perform local signal conditioning, multiplexing and digital communications has been particularly helpful. These devices, adapted from touch-screens, are small enough to be located at the fingertips of a hand. One solution is to modify the barometric pressure sensing chips common in cell phones, converting them into pressure sensing elements [28.95, 176]. Another is to use processors adapted for capacitive touch screens [28.94, 103]. Still another involves arrays of optical tactile devices [28.22].

28.5 Conclusions and Future Developments

In comparison to computer vision, tactile sensing always seems to be *a few years away* from widespread adoption. As explained in the introduction to this chapter, the reasons include physical problems (placement and robustness of sensors, wiring challenges) and the diversity of sensor types for detecting forces, pressures, local geometries, vibrations, etc. As we have seen, the transduction and interpretation methods are typically different for each of these tactile quantities. However, there are some basic issues that apply to tactile sensing in general. For example, sensors are generally located within or beneath a compliant skin, which affects the quantities that they sense in comparison to pressures, stresses, thermal gradients or displacements applied to the skin surface.

When choosing tactile sensors for a robot arm or hand, it is effective to begin with a consideration of which tactile quantities are most desired and for what purpose. For example, if the main concern is to obtain accurate measurements of loads or contact forces

at sufficient data rates for force servoing, then intrinsic tactile sensing may make the most sense. If manipulating objects with soft contacts and with sliding or rolling, curved array sensors for measuring pressure distributions, or perhaps local skin deflections, may be desirable. If exploring objects to learn about their texture and material composition, dynamic tactile sensors and thermal sensors may be effective.

In an ideal world, one would incorporate all these tactile sensors in a robotic end-effector without regard to cost, signal processing or wiring complexity. Fortunately, the cost and size of transducers suitable for tactile sensing are steadily dropping and the ability to perform localized processing is improving with surface-mounted devices on flexible circuits. In the near future it will be increasingly possible to fabricate dense arrays of transducers in-situ on contoured surfaces, using material deposition and laser machining techniques. In this way, robots may finally start to approach the tactile sensitivity and responsiveness of animals.

29. Inertial Sensing, GPS and Odometry

Gregory Dudek, Michael Jenkin

This chapter examines how certain properties of the world can be exploited in order for a robot or other device to develop a model of its own motion or pose (position and orientation) relative to an external frame of reference. Although this is a critical problem for many autonomous robotic systems, the problem of establishing and maintaining an orientation or position estimate of a mobile agent has a long history in terrestrial navigation.

29.1 Odometry

The word *odometry* is a contraction of the Greek words *hodos* meaning *travel* or *journey*, and *metron* meaning measure. Given its importance to a wide variety of applications from civil engineering to military conquest, the basic concepts that underly odometry have been studied for over 2000 years. Perhaps the earliest reference to odometry appears in his *Ten Books on Architecture* where *Vitruvius* describes [29.1]

a useful invention of the greatest ingenuity, transmitted by our predecessors, which enables us, while sitting in a carriage on the road or sailing by sea, to

know how many miles of a journey we have accomplished.

In the context of autonomous vehicles, odometry usually refers to the use of data from the actuators (wheels, treads, etc.) to estimate the overall motion of the vehicle. The basic concept [29.2] is to develop a mathematical model of how commanded motions of the vehicles wheels/joints/etc. induce motion of the vehicle itself, and then to integrate these commanded motions over time in order to develop a model of the pose of the vehicle as a function of time. The use of odometry infor-

Fig. 29.1 Differential drive kinematics

mation to estimate the pose of the vehicle as a function of time is known as *Dead Reckoning* or *Deductive Reckoning* and finds wide application in navigation at sea [29.3].

The details of odometry estimation varies with vehicle design. In the context of mobile robots perhaps the simplest vehicle for odometry estimation is the differential drive vehicle (Fig. 29.1). A differential drive vehicle has two driveable wheels which are independently controllable and which are mounted along a common axis. Assuming that the location of the wheels are fixed on the vehicle, then for the wheels to remain in constant contact with the ground, the two wheels must describe arcs on the plane such that the vehicle rotates around a point (known as the ICC – instantaneous center of curvature) that lies on the wheels' common axis (Fig. 29.1). If the ground contact speeds of the left and right wheels are v_l and v_r respectively, and the wheels are separated by a distance $2d$, then

$$\omega(R + d) = v_r ,$$

$$\omega(R - d) = v_l .$$

We can rearrange these two equations to solve for ω the rate of rotation about the ICC and R the distance from the center of the robot to the ICC

$$\omega = (v_r - v_l)/2d$$

$$R = d(v_r + v_l)/(v_r - v_l) .$$

The instantaneous velocity of the point midway between the robot's wheels is given by $V = \omega R$.

Now as v_l and v_r are functions of time we can generate the equation of motion for the differential drive robot. Using the point midway between the wheels as the origin of the robot, and writing θ as the orientation of the robot with respect to the x -axis of a global Cartesian coordinate system obtains

$$x(t) = \int V(t) \cos [\theta(t)] dt ,$$

$$y(t) = \int V(t) \sin [\theta(t)] dt ,$$

$$\theta(t) = \int \omega(t) dt .$$

This is the solution for the odometry of a differential drive vehicle on the plane. Given control inputs (v_l and v_r) and some initial state estimate, we can estimate where an idealized robot using this motion model will be at any time t .

Given such a model and complete knowledge of the control inputs, we should, in principle, be able to estimate a robot's pose at any time. In a perfect world this would be all that is necessary to estimate accurately the robot's pose at any time in the future. Unfortunately errors in the modelling (incorrect estimations of wheel size, vehicle size), uncertainty about the control inputs, realities of the motor controller (errors between commanded wheel rotation and true rotation), errors in the physical modelling of the robot (wheel compaction, ground compaction, wheel slippage, non-zero tire width), etc., introduces an error between the dead reckoning estimate of the vehicle motion and its true motion. The problem of correcting for this error is the problem of *pose maintenance* for the vehicle, and requires the integration of the dead reckoning estimate with estimates obtained from other sensor systems.

Other chapters in this handbook examine sensors that rely on external events, visual and otherwise, that can provide information as to the robot's pose or changes in its pose. Here we consider sensors that transduce physical properties of matter under the influence of external forces and properties of matter and the use of global positioning systems (GPS).

29.2 Gyroscopic Systems

The goal of gyroscopic systems is to measure changes in vehicle orientation by taking advantage of physical laws that produce predictable effects under rotation. A rotating frame is not an inertial frame, and thus many physical systems will appear to behave in an apparently *non-Newtonian* manner if the frame is rotating. By measuring these deviations from what would be expected in a Newtonian frame the underlying self-rotation can be determined.

29.2.1 Mechanical Systems

Mechanical gyroscopes and gyrocompasses have a long history in navigation, *Bohnenberger* is generally credited with the first recorded construction of a gyroscope [29.4]. The gyrocompass was patented in 1885 by Martinus Gerardus van den Bos. In 1903 Herman Anschütz-Kaempfe constructed a working gyrocompass and obtained a patent on the design. In 1908 Elmer Sperry patented a gyrocompass in the US and then attempted to sell this device to the German Navy. A patent battle followed and Albert Einstein testified in the case. ([29.5–8] for more details on the history of the gyrocompass and its inventors.)

Gyroscopes and gyrocompasses rely on the principle of the conservation of angular momentum [29.9]. Angular momentum is the tendency of a rotating object to keep rotating at the same angular speed about the same axis of rotation in the absence of an external torque. The angular momentum L of an object with moment of inertia I rotating at angular speed ω is given by

$$L = I \times \omega.$$

Consider a rapidly spinning wheel mounted on a shaft so that it is free to change its axis of rotation (Fig. 29.2a). Assuming no friction on the bearings or air resistance, the rotor axis will remain constant regardless of the motion of the external cage. This constancy of orientation can be exploited to maintain a bearing independently of the motion of the vehicle, although it is not usually desirable to utilize the principle of conservation of angular momentum via a gyroscope directly. To see this, suppose that a gyroscope is set on the equator, with its spinning axis aligned pointing along the equator (Fig. 29.2b). As the earth spins, the gyroscope will maintain a constant axis of orientation and thus to an earth-fixed observer will appear to rotate returning to its original orientation every 24 hours. Similarly, if the gyroscope were to be positioned on the equator such that its spinning axis was parallel to the axis of rotation of the earth, the gyroscope's axis of rotation would re-

main stationary and would appear to remain stationary to an earth-fixed observer as the planet rotates.

Although this global motion limits the mechanical gyroscope's ability to sense absolute orientation directly, gyroscopes can be used to measure local changes in orientation, and thus are well suited to vehicular robotic applications. Rate gyros (**RGs**) measure a vehicle's rotation rate (its *angular rate* of rotation). This is the fundamental measurement that is the basis of all gyroscopic systems. Rate-integrating gyros (**RIGs**) use embedded processing to internally integrate the angular rotation rate to produce an estimate of the absolute angular displacement of the vehicle.

In order to exploit a gyroscope for navigation with respect to an earth-stable frame, it is desirable for the rotational axis of the shaft to remain fixed within the earth frame, rather than remaining fixed with respect to an external frame. A gyrocompass obtains this by relying on precession. When a torque is applied to change the axis of rotation of a spinning object, conservation of angular momentum will cause a change in the spin direction that is perpendicular to the angular momentum and the direction in which the torque is applied. This is the effect that causes gyroscopes suspended at one end to *spin* around the end from which they have been suspended. Consider the *pendulus gyro* sketched in Fig. 29.3a. This is a standard gyroscope with a weight suspended below the rotational axis. As before, imagine this pendulus gyrocompass set spinning on the equator with the axis of rotation aligned with the axis of rotation of the planet, and with the weight hanging directly down. As the planet spins, the gyroscope's axis of rotation remains stationary and would appear to remain

Fig.29.2a,b Mechanical gyroscope. (a) Traditionally gimbaled gyroscope. The gimbal provides the gyroscope the freedom to rotate about its axis as the base of the gyroscope is rotated (b) gyroscope as it is rotated around the planet. The wheel of the gyroscope (grey) remains in the same orientation as it revolves with the planet. To an observer on the planet the gyroscope will appear to rotate

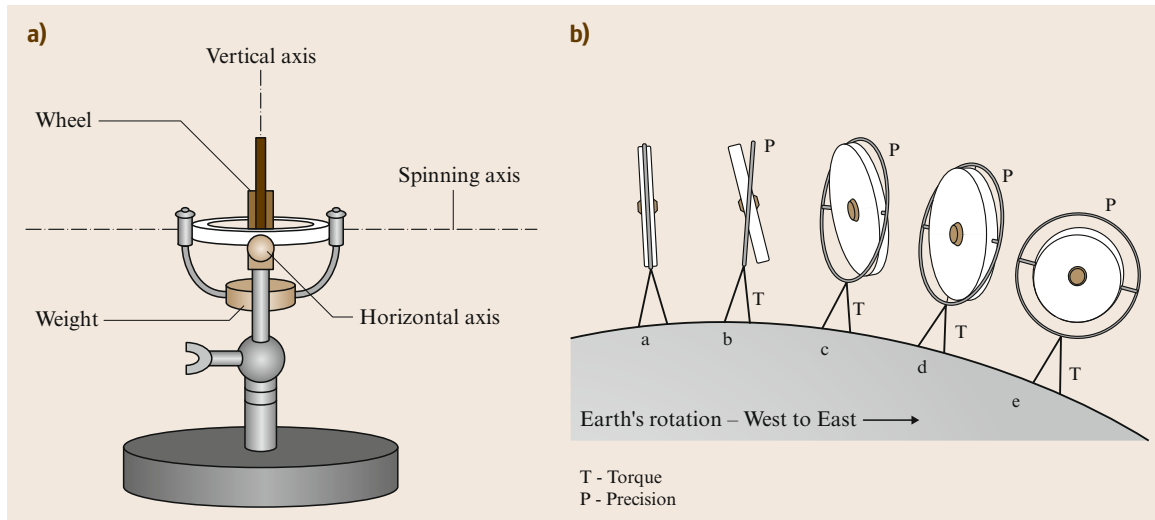

Fig.29.3a,b Simple gyrocompass: (a) Pendulus gyro; (b) Precessional motion

stationary as the planet rotates. Now suppose that instead of being aligned with the spin axis of the planet, the spin axis is aligned with the equator. As the planet spins, the spin axis is drawn out of the plane as it remains aligned with the original spin axis. As it becomes drawn out of the plane, the mass hanging below the gyrocompass is raised up and generates a torque down due to gravity. The direction perpendicular to the spin axis and the torque rotates the spin axis away from the equator (aka towards the true pole). This process is sketched in Fig. 29.3b.

Unfortunately the pendulus gyro is not an ideal device for navigation. Although its rotation axis will align with the rotation axis of the planet, it does not converge to this value directly but oscillates about it. The solution to this damping problem is to use oil reservoirs, rather than a solid weight, as the counterbalance, and to restrict the motion of the oil in the reservoir [29.10].

The gyrocompass finds true north by controlling the precession of a gyroscope. In practice, the performance of a mechanical gyrocompass is impacted by external forces acting on the compass which also contribute to the precession of the gyroscope. This includes forces generated by motion of the device containing the gyrocompass, as well as any external forces acting on the vehicle. Another issue for mechanical gyrocompasses is that in latitudes away from the equator, the stable position of the gyrocompass is not horizontal, and accurate estimates of true north in such latitudes requires corrections to be applied to raw gyrocompass values. Finally, mechanical gyrocompasses require an external force to be applied to maintain the spin of the gyroscope. This process introduces unwanted forces into the system which can further corrupt the measurement process.

Given the complexity, cost, size, the delicate nature of gyrocompasses, and the availability of less expensive and more reliable technologies, mechanical gyrocompasses have given way to optical- and MEMS-based systems (MEMS or *microelectromechanical systems* are also known as *micromachines* or *micro systems technology* and refer to mechanisms at the scale of integrated circuits).

29.2.2 Optical Systems

Optical gyroscopes rely on the *Sagnac effect* rather than rotational inertia in order to measure (relative) heading. The mechanism is based on the behaviour of an optical standing wave in a rotating frame. Historically this was first produced using lasers and an arrangement of mirrors, but it is now typically obtained using fibre-

Fig.29.4a,b Circular light path. (a) Stationary path; (b) Moving path

optic technology. The Sagnac Effect is named after its discoverer *Georges Sagnac* [29.11, 12]. The underlying concept can be traced back even earlier to the work of *Harress* [29.13], and perhaps finds its most famous application in terms of the measurement of the rotation of the earth [29.14].

Ignore relativistic effects and consider the circular light path shown in Fig. 29.4a. If two light pulses are sent in opposite directions around a stationary path of perimeter $D = 2\pi R$ they will travel the same distance at the same speed. They will arrive at the starting point simultaneously, taking time $t = D/c$ where c is the speed of light in the medium. Now let us suppose that instead of being stationary, this circular light path rotates clockwise about its center at rotational speed ω (Fig. 29.4b). The light travelling clockwise around the path must go *farther* to reach the starting point, while light travelling counterclockwise around the path goes a *shorter* distance. The clockwise path has distance

$$D_c = 2\pi R + \omega R t_c ,$$

where t_c is the time taken in the clockwise direction, while the counterclockwise path has distance

$$D_a = 2\pi R - \omega R t_a ,$$

where t_a is the time taken in the counterclockwise direction. But $D_c = c t_c$ and $D_a = c t_a$, so

$$t_c = 2\pi \frac{R}{c - \omega R}$$

and

$$t_a = 2\pi R(c + \omega R) .$$

The time difference $\Delta t = t_c - t_a$ is given by

$$\Delta t = 2\pi R \left(\frac{1}{c - \omega R} - \frac{1}{c + \omega R} \right) .$$

By measuring Δt , the rotational speed can be computed. Note that although the above derivation assumes classical mechanics and ignores relativistic effects, the derivation also applies when relativistic speeds are taken into account [29.15]. See [29.16] for an in depth review of the Sagnac effect and ring-lasers.

In optical gyroscopes lasers are typically used as the light source. Optical gyroscopes either utilize straight line light paths with mirror surfaces or prisms at the edges to direct the light beam (a ring laser gyroscope – **RLG**), or a polarization maintaining glass-fiber loop

(fiber optic gyro – **FOG**). The glass-fiber may actually loop multiple times, thus extending the effective length of the light path. The time delay between the clockwise and counter-clockwise is detected by examining the phase interference between the clockwise and counter-clockwise light signals. Multiple optical gyroscopes with non-parallel axes can be ganged together in order to measure 3-D rotations.

Various techniques can be used to measure the time difference including examining the Doppler (frequency) shift of the laser light due to the motion of the gyro and an examination of the beat frequency of the interference pattern between the clockwise and counter-clockwise paths [29.17]. Ring interferometers typically consist of many windings of fiber optic lines that conduct light of a fixed frequency in opposite directions around the loop and measure the phase difference. A ring laser consists of a laser cavity in the shape of a ring. Light circulates in both directions around this cavity producing two standing waves with the same number of nodes in both directions. Since the optical path lengths are different in the two directions, the resonant frequencies differ. The difference between these two frequencies is measured. An unfortunate side effect of the ring laser approach is that the two signals will lock to each other for small rotations and it is typically necessary to physically rotate the device in a controlled manner in order to ensure that this lock-in effect can be avoided.

29.2.3 MEMS

Almost all **MEMS** gyroscopes are based on vibrating mechanical elements to sense rotation. Vibratory gyroscopes rely on the transfer of energy between vibratory modes based on Coriolis acceleration. Coriolis acceleration is the apparent acceleration that arises in a rotating frame of references. Suppose an object moves along a straight line in a rotating frame of reference. To an outside observer in an inertial frame the object's path is curved – thus there must be some force acting on the object to maintain the straight line motion as viewed by the rotating observer. An object moving in a straight line with local velocity \mathbf{v} in a frame rotating at rate $\mathbf{\Omega}$ relative to an inertial frame will experience a Coriolis acceleration given by

$$\mathbf{a} = 2\mathbf{v} \times \mathbf{\Omega} .$$

Transducing acceleration in a **MEMS** gyroscope amounts to inducing some local linear velocity and measuring the resultant Coriolis forces.

Early **MEMS** gyroscopes utilized vibrating quartz crystals to generate the necessary linear motion. More

Fig. 29.5 MEMS gyroscope principle of operation

recent designs have replaced the vibrating quartz crystals with silicon based vibrators. Various MEMS structures have been developed including

Tuning Fork Gyroscopes

Tuning fork gyroscopes use a tuning fork-like structure (Fig. 29.5) as the underlying mechanism. As the tuning forks vibrate within a rotating frame, Coriolis forces cause the tines of the fork to vibrate out of the plane of the fork which is measured. This is the effect used by the InertiaCube sensor [29.18].

Vibrating Wheel Gyroscopes

Vibrating wheel gyroscopes use a wheel that oscillates about its rotational axis. External rotation of the frame causes the wheel to tilt which can be sensed.

Wine Glass Resonator Gyroscopes

Wine glass resonator gyroscopes use the effect of Coriolis forces on the position of nodal points on a resonating structure to estimate the external rotation. Sadly, no actual wine glasses are involved.

As MEMS gyroscopes have no rotating parts, have low power consumption requirements, and are very small, MEMS gyros are quickly replacing mechanical and optical gyroscope sensors in robotic applications.

With the exception of gyrocompasses, gyroscopes measure relative rotational motion around a single axis. They accomplish this measurement by exploiting physical properties of rotating frames of reference. Earlier technologies based on mechanical gyroscopes have given way to optical- and MEMS-based devices but the underlying principle remains unchanged – that rotating frames of reference show specific physical properties can be measured to estimate the relative rotation.

A problem common to all gyroscopes is that of drift. Each of the relative motion measurements is corrupted by an error process, and these errors accumulate over time. This, coupled with specific measurement errors associated with the individual gyroscope technologies means that unless the error is corrected through reference to some alternate (external) measurement, the drift will eventually exceed the required accuracy of the measurement.

As individual gyros only measure rotation about a single axis, it is common to gang multiple gyros together with orthogonal axes of sensitivity in order to measure 3-D rotations. These collections of gyros are often integrated with other sensors (compasses, accelerometers, etc.) in order to construct *inertial measurement units* (or IMUs). This is considered in Sect. 29.4.

29.3 Accelerometers

Just as gyroscopes can be used to measure changes in orientation of a robot, other inertial sensors – known as *accelerometers* – can be used to measure external forces acting on the vehicle. One important factor concerning accelerometers is that they are sensitive to all external forces acting upon them – including gravity. Accelerometers use one of a number of different mechanisms to transduce external forces into a computer readable signal.

29.3.1 Mechanical Accelerometer

A mechanical accelerometer (Fig. 29.6a) is essentially a spring-mass-damper system with some mechanism

for external monitoring. When some force is applied (e.g., gravity), the force acts on the mass and displaces the spring. Assuming an ideal spring with a force proportional to its displacement, the external forces balance the internal ones

$$\begin{aligned} F_{\text{applied}} &= F_{\text{inertial}} + F_{\text{damping}} + F_{\text{spring}}, \\ &= m\ddot{x} + c\dot{x} + kx, \end{aligned}$$

where c is the damping coefficient. This equation can be solved to show that depending on the size of the damping coefficient relative to the expected external force and the mass, the system can be made to reach a stable final value in a reasonably short period of time when-

Fig. 29.6 Accelerometers. (a) Mechanical accelerometer; (b) piezoelectric accelerometer ◀

ever a static force is presented. This need to pre-estimate the expected force and the resulting (potentially long) time for the system to converge on a final measurement coupled with non-ideal performance of the spring limits the applicability of mechanical accelerometers. Another issue with mechanical accelerometers is that they are particularly sensitive to vibration.

29.3.2 Piezoelectric Accelerometer

Rather than relying on a direct mechanical measurement of external forces, piezoelectric accelerometers are based on a property exhibited by certain crystals which generate a voltage across them when stressed. A small mass can be positioned so that it is only supported by the crystal, and as forces cause the mass to act upon the crystal this induces a voltage that can be measured (Fig. 29.6b).

29.4 IMU Packages

An inertial measurement unit (IMU) is a device that utilizes measurement systems such as gyroscopes and accelerometers to estimate the relative position, velocity and acceleration of a vehicle in motion. First demonstrated in 1949 by C. S. Draper, IMU's have become a common navigational component of aircraft and ships. Historically an IMU is self-contained and provides this estimate without reference to external references, however the definition has become less precise in recent years and now it is common to have the term IMU also refer to systems which do include such external references.

IMU's come in two basic flavours, gimballed systems and strap-down systems. As their name suggests, gimballed IMU's are mounted within complex gimball structures in order to provide a stable platform from which measurements can be made. Gyroscopes are used to ensure that the gimball remains aligned with the initial reference frame at power up. The orientation of the gimballed platform relative to the vehicle is used to map measurements taken within the IMU to the reference frame of the vehicle. Strap down IMU's, on the other hand, have the IMU rigidly connected to the vehicle (strapped down), so no such transformation is required. In either case estimating the motion relative to the initial frame requires integrating information from the sensors within the IMU (accelerometers, gyroscopes, etc.) in real time. This was a significant computational ef-

fort in the early days of IMU's, and thus historically (prior to the 1970s) the gimballed IMU was more common. Given the low expense of such computation today, and the costs associated with manufacturing and operating gimballed IMU's, strap down IMU's are much more common today [29.19].

The sensing technology of an IMU is typically integrated with an on-board computational unit to produce an attitude and heading reference unit (AHRS) which is a single device that maintains a 6-DOF estimate of the pose of the vehicle (position (x, y, z) and orientation (roll, pitch, yaw)). In practice, the distinction between an AHRS and an IMU is often unclear since the combinations of software and device outputs is quite varied, and most MEMS devices contain a substantial computational substrate and are able to directly offer up a position, velocity, and attitude (PVA) solution. In general, an AHRS includes gyroscopes, accelerometers and a magnetometer. These are often combined with a GPS as described in the next section. In addition to maintaining a 6-DOF pose of the vehicle, commercial IMU's also typically maintain estimates of velocity and acceleration and can usually provide a diverse set of lower-level measurements as well.

The basic computational task of an IMU is shown in Fig. 29.7. This IMU uses three orthogonal accelerometers and three orthogonal gyroscopes. The Gyroscope data ω is integrated to maintain an ongoing estimate

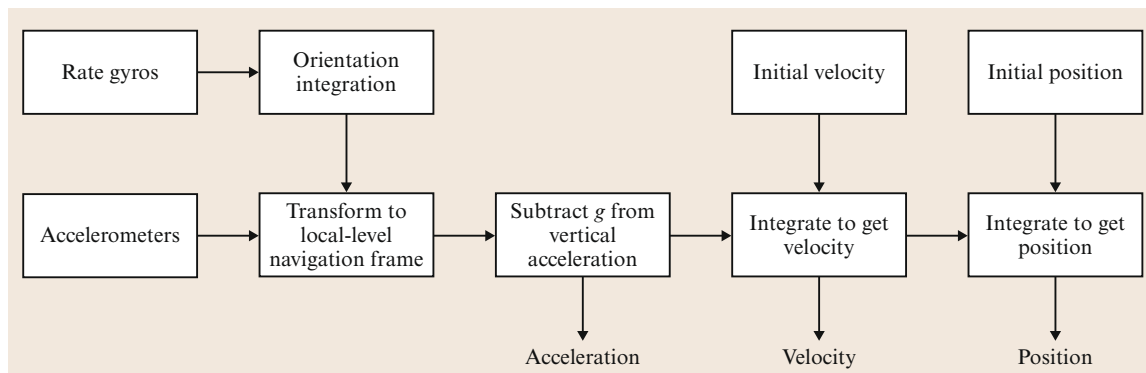

Fig. 29.7 IMU block diagram

of vehicle orientation θ . At the same time, three accelerometers are used to estimate the instantaneous vehicle acceleration \mathbf{a} . This data is then transformed via the current estimate of the vehicle orientation relative to gravity, so that the gravity vector can be estimated and extracted from the measurement. The resulting acceleration is then integrated to obtain vehicle velocity \mathbf{v} and then integrated again to obtain position \mathbf{r} .

IMU's are extremely sensitive to measurement errors in the underlying gyroscopes and accelerometers. Drift in the gyroscopes leads to mis-estimates of the vehicle orientation relative to gravity, resulting in an incorrect cancellation of the gravity vector. As the accelerometer data is integrated twice, any residual gravity vector will result in a quadratic error in position [29.18]. As it is never possible to completely eliminate the gravity vector and this and any other error is integrated over time drift is a fundamental issue for any IMU. Given a sufficiently long period of operation all IMU's eventually drift and reference to some external measurement is required to correct this. For many field robots GPS has become an effective source for these external corrections.

29.4.1 Performance

Gyroscopes and Inertial measurements units today frequently include the required computational support to directly integrate the inertial signals and provide position, velocity, and attitude (PVA) estimates as direct output. The quality of these estimates is critically de-

pendent not only on the sensing technology, but on the algorithms (almost universally including an extended Kalman filter) used in the estimation process and their calibration. While the extended Kalman filter is, of course, a well understood algorithm, the subtlety of its implementation remains a significant distinguishing factor among different brands of IMU.

Inertial measurement units can be evaluated with respect to various factors that determine performance. Several of these are enumerated below:

1. Bias repeatability. This is maximum deviation of the gyroscope under fixed inertial operation conditions with constant temperature, i. e., the drift of the reading under ideal conditions. This is measured over different time scales and leads to *short term* and *long term* bias repeatability.
2. Angle random walk. This measures the noise in the angular rate data coming from the gyro.
3. Scale factor ratio. This parameter is not specific to IMU's or gyros and is a general measurement of signal amplitude. It measures the ratio of the output analogue voltage to the sensor parameter of interest. For a gyroscope this is typically measured in mV/(deg/s) whereas for an accelerometer it is typically mV/(m/s²).
4. Position accuracy. The accuracy in practice of position estimation depends on the sensors and the integration algorithm, both of which are intrinsic to the IMU, as well as the nature of the trajectory experienced by the IMU.

29.5 Satellite-Based Positioning (GPS and GLS)

The global navigation satellite system (GNSS) and it's most commonplace instance, the global positioning system (GPS), is the single most commonly used

mechanism for location estimation. It provides a three dimensional position estimate in absolute coordinates as well as current time and date and is available any-

where on the earth's surface. Standard GPS provides a position estimate in the horizontal plane to within about 20 meters. It was originally developed for military applications but has become widely adopted in civilian applications including automobile navigation systems, recreational orienteering, and inventory tracking for transportation companies. It is rapidly being superseded (via augmentation) by systems that add related technologies to basic GPS reception.

29.5.1 Overview

GPS is based on received radio signals transmitted by an ensemble of satellites orbiting the earth. By comparing the time delays from the different satellite signals, a position fix can be computed. The most widely accepted GPS system is based on the NAVSTAR satellite system deployed and maintained by the United States, specifically by the Air Force Space Command. As a US military service, the US government reserves the right to terminate or modify its availability at their discretion. A similar system named GLONASS (globalnaya navigatsionnaya sputnikovaya sistema) is operated by the Russian government. Many modern GPS receivers and cell phones can access both the US GPS and Russian GLONASS systems. Another alternative system is being deployed by the European Union, named Galileo, with the explicit expectation that it not be under military control. It is expected to offer two different classes of service, an open service and an encrypted higher-quality commercial service. Other GPS systems such as the Chinese Beidou, the Japanese quasi-zenith satellite system (QZSS), the Indian regional navigational satellite system (IRNSS) system are intended to provide similar functionality. GPS receivers that are able to receive position data from multiple different satellite systems have become readily available and are referred to as global navigation satellite system (GNSS) systems.

Technically, the term GPS always refers to the NAVSTAR system although in common parlance it is sometime used to refer to any system that provides satellite-based positioning. Historically NAVSTAR provided two different services: the precise positioning system (PPS), reserved primarily for military users, and the standard position system (SPS) with lower accuracy. The difference between these was referred to as selective availability (SA). This difference in accuracy was artificially induced via pseudo-random noise in the SPS signal for strategic reasons, and was eliminated on May 2, 2000. Although this accuracy distinction could, in principle, be reinstated this seems unlikely, and recent GPS satellites (GPS Block III series, not launched at this time) are not equipped with the SA feature. US mil-

itary users have access to a precise positioning service (PPS). This second frequency enables military users to correct for radio signal degradation caused by the Earth's atmosphere.

The GPS satellite network is based on a base constellation of 24 orbiting satellites along with up to six supplementary additional satellites that are also operational. These satellites are in almost-circular medium earth orbit. As opposed to being geostationary the orbits are semi-synchronous, meaning that their position relative to a ground observer is constantly changing, and that their orbital period is exactly half a sidereal day. The orbits are selected so that from almost any point of the earth's surface there will always be four or more satellites directly visible – a criterion for obtaining a GPS position estimate. The satellites are organized into six orbital planes with four satellites in each. The system is designed such that averaged over the entire earth's surface and over a 24 hour interval, the satellites should provide 99.9% coverage at the worst-covered location in any 24 hour interval, and the signal should be at least 83.92% available at the worst place on earth on the worst day over a 30 day measurement interval. Note that this criterion for availability takes into account transmitted operational factors above and beyond simple coverage. Of course, this criterion ignores the reality of topographic features like mountains, as well as other objects such as buildings that can obstruct the line-of-sight.

Each satellite repeatedly broadcasts a data packet known as the coarse-acquisition (C/A) code, which is received by the GPS receiver on the L1 channel at 1575.42 MHz. The simple principle is that if the receiver knows the absolute positions of the observed satellites, the receiver position can be directly determined. If the signal propagation time for the radio signals were known, the receiver position could be computed directly via trilateration (Fig. 29.8). This implies that an absolute timing reference is present on the receiver, which would be prohibitively costly. Instead, only the satellites have highly accurate atomic clocks. The receiver computes the difference in signal propagation times between the different satellites, and uses this to compute a range estimate referred to as a *pseudo-range* (to explicitly indicate that it is corrupted by several sources of measurement noise). The specific geometric problem is referred to as *multilateration* or *hyperbolic positioning* and the solution is computed using a sophisticated Kalman filter within the GPS receiver. To avoid retaining an ephemeris (pose) table for the satellites and a very accurate clock in the receiver, each satellite broadcasts its own position and an accurate time signal as part of the data packet that it transmits.

GPS satellites broadcast at several different frequencies known as L1 through L5 although until recently only L1 (1575.42 MHz) and L2 (1227.6 MHz) were being used for civilian GPS receivers. Dual frequency L1/L5 GPS systems have become more broadly largely due to the emergence of other GNSS systems in addition to the original NAVSTAR GPS.

The standard service offered by NAVSTAR and the performance criteria for it are determined by the L1 signal, which contains two unencrypted components: the acquisition message (coarse acquisition message C/A) and a navigation data message. It is also possible to use the encrypted L2 signal as well, even without the secret decryption keys, to provide augmented error correction (by observing the relative effects of ionospheric distortion as a function of frequency). The restricted access signal broadcast on both the L1 and L2 channels is the P-code (as well as a fairly recent M-code) which, is known as the Y-code or P(Y) or

P/Y code once it is encrypted. Both the C/A and P(Y) code include the navigation message stream that specifies clock bias data, orbital information, ionospheric propagation corrections factors, ephemeris data, status information on all the satellites, universal time code and other information. The satellite performance is coordinated by the master control station located at the Schriever Air Force Base near Colorado Springs, (Colorado, USA) and is connected to a global network of five additional monitoring stations (Cape Canaveral, Ascension Island, Kwajalein Atoll (Marshall Islands), Diego Garcia Atoll, Hawaii) which are used to produce the measurements that are uplinked to generate the navigation message stream. Finally, it should be noted an additional signal is now available on the L2 frequency band. This L2C signal on satellites designated *block IIR-M* promises to provide much improved receiver sensitivity so that position fixes can be obtained in environments, such as in forests, where they are currently not readily available.

29.5.2 Performance Factors

GPS performance depends on several factors: satellite transmission accuracy, environmental conditions, interactions with ground-based obstacles, and receiver properties.

In the context of robotics, factors that effect the performance of the satellites themselves and the atmospheric conditions are essentially uncontrollable. Nevertheless, it should be noted that these can be sources of error and that the GPS signal itself may not always be reliable. A *service failure* is defined as a set of circumstances where the positioning service exhibits atypical error behavior (i. e., incorrect signals). Such failures are classified into minor and major failures. Minor failures are those that have limited impact on a receiver and lead to ranging error of under 150 m. Major failures are those that lead either to larger errors or data processing overloads in the receiver. If a single satellite experiences an error that leads to a major failure, then within a 6 hour period, approximately 63% of the earth's surface will have the satellite in view at some point.

The controllable factors in using GPS for accurate localization are (i) it requires an unobstructed line of sight to the satellites, (ii) it depends on atmospheric conditions, and (iii) it depends on the ability to receive (weak) radio-frequency communications. There is a potential for wildly incorrect estimates. Generally satellites that are directly overhead provide better signal than those near the horizon. In addition, since the basis of GPS position is differential signal analysis, it is best if the satellites used in the GPS computation are widely spaced in the sky.

Fig. 29.8 GPS trilateration on the plane. Suppose that one receives signals from three transmitters (A, B, and C) with known locations. Knowledge of the signal delay from one emitter (say A) localizes the receiver to lie on a circle of known diameter (d_A) whose center is the emitter. The constraints from two emitters intersect at two points (maximum). A third emitter is required to disambiguate these two solutions. In 3-D, the signal propagation constraint from a single emitter constrains the receiver to lie on a sphere. The intersection of the constraints from two emitters constrains the receiver to lie on a circle. The intersection of the constraints from three emitters constrains the receiver to one of two points

GPS signals are in the microwave band and, as such, they can pass through plastic and glass, but are absorbed by water (wood, heavy foliage) and are reflected by many materials. As a consequence, GPS is unreliable in heavy forest, deep canyons, inside automobiles and boats, heavy snowfall or between tall buildings. In some cases, partial obstruction of the sky may not prevent a position estimate from being computed. Assuming the minimum number of satellites operating at any time is 24, then on average across the earth's surface 8 satellites are in view so that even partial occlusion of the sky can often be tolerated. On the other hand, partial occlusion can lead to reduced accuracy since the selection of available satellites used for computing position becomes limited and optimal accuracy is obtained by using as many satellites as possible (weighting them appropriately in the internal Kalman filter).

Secondary factors that differentiate different GPS receivers are the rate at which the signals are collected, the receiver sensitivity, the number of satellites used in the final computation, the number of factors taken into account in the estimator and the exploitation of supplementary positioning schemes such as WAAS (described later). A major factor in determining the rate at which estimates can be produced is the number of independent receiver elements in the GPS system. Sequential single-channel receivers are simpler and thus more economical (and potentially smaller), but they must sequentially lock onto each satellite being used. Parallel multi-channel receivers can lock onto more than one satellite at once, and are generally faster and more costly; some degree of parallelism is the norm in good-quality consumer devices.

GPS computations are based on an estimation of the dilution of precision (DOP) and specifically for the dilution of precision of the positional parts of the system (i.e., positional dilution of precision PDOP). These correspond to partial derivatives of the error with respect to position and allow the most accurate ensemble of visible satellites to be determined at any time. The standard implementation for GPS systems specifies that PDOP values be recomputed every 5 minutes.

The minimum performance parameters for GPS receivers are based upon transforming instantaneous range residuals to a user position estimate using a linearized position solution from a stationary, surveyed location. Most GPS receivers use additional techniques such as range residual smoothing, velocity aiding, Kalman filtering, or multiple satellite (*all-in-view satellite*) solutions. That said, formal performance for the system is measured with respect to the minimum. The GPS position estimation algorithm is summarized as follows:

1. Select the best four satellites based upon minimum error measured in terms of PDOP.
2. Update every five minutes, or whenever a satellite being used in the solution sets.
3. Measure the pseudo range to each satellite. Each of the four measurements must have a reception timetag within 0.5 s of the solution time. The reception timetag is based upon measurement system time, and the transmission timetag is based upon satellite time.
4. Determine the ephemeris for each of the satellites being used, and compute the Earth-centred, Earth-fixed (ECEF) coordinates for each. Correct for the earth's rotation and thus compute an estimate pseudo-range measurement that should be obtained for each satellite.
5. Compute the *range residuals* as the differences between the actual and observed measurements.
6. Estimate the matrix \mathbf{G} that determines the overall system solution, known as the *position solution geometry matrix*. The matrix can be described in terms of a collection of row vectors one for each of the satellites being used, each row being made up of the x, y, z and time coordinate direction cosines for the vector between the user and the satellite (the is with respect to a fixed reference frame for the planet called the World Geodetic System, WGS84). WGS84 represents position on the Earth in terms of latitude, longitude, and height above the surface, which is modeled as an ellipsoid. The WGS84 coordinate system represents longitude as a value from -180 to 180 degrees, with 0 degrees at the Earth's prime meridian, and longitude as a value from 90 degrees (at the North pole) to -90 .
7. Compute the user position.

The standard implementation of GPS is based upon a position fix rate of once per second, although faster and slower rates are possible. Under typical operating conditions and without specialized enhancements GPS accuracy is roughly 20–25 m in the horizontal plane and 43 m in the vertical direction. The restricted PPS signal provides an accuracy of at least 22 m (typical values are 7–10 m) in the horizontal plane and 27.7 m in the vertical direction as well as UTC time accuracy within 200 ns based on a reference signal from the US Naval Observatory.

GPS signals can be affected by multipath issues, where the radio signals reflect off surrounding terrain – buildings, canyon walls, hard ground, etc. This delay in reaching the receiver causes inaccuracy. A variety of receiver techniques, most notably narrow correlator spacing [29.20], have been developed to mitigate multipath errors. For long delay multipath, the receiver itself

can recognize the wayward signal and discard it. To address shorter delay multipath due to the signal reflecting off the ground, specialized antennas may be used. This form of multipath is harder to filter out as it is only slightly delayed as compared to the direct signal, causing effects almost indistinguishable from routine fluctuations in atmospheric delay.

29.5.3 Enhanced GPS

A wide range of augmentation systems have been developed both by government agencies and private companies to enhance the basic GPS signal.

Wide Area Augmentation System (WAAS)

The wide area augmentation system (WAAS) is an augmentation system operated by the US Federal Aviation Administration (FAA) to provide better GPS and timing performance for aircraft operating over North America. The WAAS system is based around a supplementary signal that can be received by GPS receivers to improve their accuracy. WAAS increases the accuracy of horizontal position estimates from 10–12 m with GPS alone, to between 1 and 2 m. The WAAS signal contains corrections for the GPS signal that reduce the effects of errors due to timing errors, satellite position corrections, and local perturbations due to variations in the ionosphere. These correction terms are estimated by ground-based stations at fixed and accurately-known positions and uplinked to satellites which broadcast them to suitably enabled GPS receivers. The WAAS signal is only computed and available for North America, but similar correction signals are becoming available elsewhere as part of the standardization of satellite-based augmentation systems (SBASs). This includes Europe (where it is called EGNOS, the European Geostationary Navigation Overlay Service) and Japan and parts of Asia (where it is called MSAS, the multi-functional satellite augmentation system). Further enhancements to GPS and WAAS, in the form of global navigation satellite system landing system (GLS), are slated for completion in 2013.

Differential GPS

Differential GPS (DGPS) is a technique for correcting GPS signals by using a nearby GPS receiver located at a known accurately-surveyed position. In fact, several variations on this basic idea exist and are also known under the general rubric of ground based augmentation systems (GBASs). DGPS uses the same principles as WAAS but on a local scale without resorting to the use of satellite uplinks. The receiver at the known position computes the error in the GPS signal and transmits it to the nearby receiver at the unknown location. Since the

error varies as a function of position on the earth, the effectiveness of the correction degrades with distance, typically with a maximum effective range of a couple of hundred miles. The method was especially desirable before the suspension of selective availability and the development of WAAS (which can be viewed as a form of DGPS). In the USA and Canada, a network of ground based DGPS transmitters are in place, send signals using radio frequencies between 285 and 325 kHz. Commercial DGPS solutions also exist akin to WAAS.

29.5.4 Nationwide Differential GPS System (NDGPS)

The (US) nationwide differential GPS system (NDGPS) is an augmentation system that integrates costal and ground transportation systems to provide 10–15 cm accuracy throughout most of the US. The system relies on a network of radio signals broadcast from base stations. Similar systems exist in a number of other countries including Canada.

Receiver Autonomous Integrity Monitor (RAIM)

Receiver autonomous integrity monitor (RAIM) is a technique by which multiple pseudo-range measurements are obtained (i. e., pose estimates) using different combinations of satellites. If inconsistent measurements are obtained, it indicates that a failure of some sort has taken place in the system. A position fix using at least satellites is needed to detect such an error which at least six satellite are needed to exclude the data from a single bad satellite and still obtain a reliable estimate.

Real-Time Kinematic Positioning (RTK)

One GPS enhancement technology with rapidly growing acceptance in robotics applications is real-time kinematic positioning or RTK [29.21]. RTK-GPS in a GNSS configuration also exploits multiple satellite constellations and is often regarded as the most high-performance GPS solution that is readily available. Because of its high accuracy, it is often referred to as *survey grade*. In practice, commonplace RTK-GPS units can achieve horizontal positioning accuracy on the order of 1 cm. RTK-GPS augments standard differential GPS technology by enhancing the effective resolution of the pseudo-range distance estimates using corrections obtained by a base station. Specifically, RTK estimates the number of carrier cycles in the communication path between a GPS satellite and each of the base station and the receiver, and thus is essentially dependent on the phase of the signal. Such units typically ignore the actual data payload of the signal and exploit the phase of the GPS signal (typically the L1 band); this is a fundamentally different mode of operation from

the commonplace code phase computation that low cost receivers use. The base station that is used to provide a reference position for the estimation process can be part of a custom system being deployed, but various networks reference base stations accessible to the public now exist. When a network of base stations are used to provide correction signals over a wide region, the system is referred to as network real-time kinematic (NRTK) GPS and a class of networks as continuously operating reference station (CORS) networks. NRTK networks are evolving rapidly and a range computing protocols have been developed or employed including the Radio Technical Commission for Maritime Services Special Committee 104 (RTCMS C104) protocol for transmitting GNSS data.

If properly estimated, RTK-GPS can obtain position estimates that are several orders of magnitude more accurate than the multiple meter accuracy associated with conventional DGPS. Critical to RTK is estimating the number of whole signal cycles that are present in the path from the satellite to the station. GPS carrier waves have a wavelength of about 19 cm, and this coupled with an estimate of the phase of the carrier signal can result in pseudo-range estimates with errors in the 1 mm range.

29.5.5 GPS Receivers and Communications

GPS receivers are classified according to their performance and cost. The best receivers are referred to as *geodetic grade* (or *survey grade*) with economical models referred to as *resource grade* or *recreational*. In general the costs of these different models varies by several orders of magnitude, but the gap in performance is gradually narrowing.

Receivers come in two types: code phase and carrier phase. Code phase receivers use the satellite navigation message part of the data stream to provide the ephemeris data and produce real-time output. There is a delay for them to lock into the satellites, but then they produce output continuously without an initial posi-

tion estimate. The C/A signal is a 1023 pseudo-random noise (PRN) bit string with a known key. The actual pseudo-range data is determined by finding the offset of this bit string, and computing the correct shift of this bit string is the essential computation that determined the delay before a lock is achieved.

Carrier phase receivers, on the other hand, use the phase of the raw GPS signal rather than the embedded (digital) C/A signal. The L1 and L2 signals have wavelengths of 19 and 24 cm respectively, and good quality phase measurements allow horizontal positioning accuracies on the order of millimeters in principle. These measurements, however, only provide relative position information within a neighborhood of some tens of kilometers.

Serial Protocols

Consumer GPS devices almost universally support some variant of the National Marine Electronics Association (NMEA) protocol as well as various proprietary protocols specific to each manufacturer. NMEA is a serial protocol sometimes encapsulated within other protocols. Several variants of the protocol exist, but NMEA 0183 is the most commonly supported while NMEA 2000 supports higher data rates and uses a very different communication protocol. While the protocol is proprietary and the official specification can only be purchased from the NMEA, there are several open-source descriptions of the protocol that have been reversed engineered and its basic message characteristics are very widely used and distributed.

The NMEA 0183 protocol supports an ASCII mode of communications based on a *talker* (the GPS receiver) and one or most *listeners* (computers) which receiver simple protocol strings called sentences. Anecdotal evidence suggests that there are ambiguities in the protocol that can lead to difficulties in assuring compatibility between devices (this suggestion is necessarily made without inspecting the proprietary documentation, which might preclude its description here).

29.6 GPS-IMU Integration

It has become commonplace for GPS and IMU technologies to be integrated into a single GPS-aided inertial navigation system (GPS/INS) to leverage their complementary advantages. Although GPS offers the promise of high resolution positioning information on or about the surface of the planet, it does not solve all of the problems associated with robot pose estimation. First, it does not directly obtain information about vehicle orientation – to determine the orien-

tation of the vehicle (yaw, and for many vehicles pitch and roll) must be estimated by either differentiating the GPS signal or through integration with other sensors including compasses, gyrocompasses, and IMU's. Second, GPS receivers are generally unable to provide continuous independent estimates of position. Estimates are only available at distinct time instances with (for inexpensive receivers at least) considerable delays between measurements. A continuous

estimate of pose requires estimation of pose between GPS readings. Finally, it is not always possible to obtain a GPS fix. Local geography (e.g., mountains, buildings, trees) or an overhead cover that is opaque to radio signals (e.g., indoors, underwater) can block the signal entirely. Integration of a GPS receiver with other sensor technology (often an IMU) can be used to deal with these issues, at least for short periods of time.

The process of integrating GPS and IMU data is typically expressed as an extended Kalman filter estimation process (Sect. 35.2.3). Essentially the IMU data is used to bridge between solid GPS measurements and is com-

bined in a least squares optimal sense with the GPS data when both are available. Given the complementary nature and true independence of the two sensors, a wide range of commercial packages have been developed to integrate GPS and IMU data [29.22].

When GPS measurements are integrated in a robotic vehicle, and in particular when they are combined with data from an IMU the orientation of the antenna becomes a consideration. The GPS position *fix* is based on the position of the GPS antenna and if it is located far from the IMU or the center of the vehicle coordinate system then this must be accounted for or instabilities in the position or orientation can occur.

29.7 Further Reading

29.7.1 Odometry

Many general robotics books including [29.2] and [29.23] provide considerable information on vehicle odometry and derive odometry equations for standard vehicle designs.

29.7.2 Gyroscopic Systems

Everett's book [29.24] provides a review of various sensor technologies including gyroscopic systems and accelerometers. Interesting historical documentation on the gyrocompass and its inventor can be found in Hughes' book [29.5].

29.7.3 Accelerometers

Everett's book [29.24] provides a review of various sensor technologies including gyroscopic systems and accelerometers.

29.7.4 GPS

Considerable details on the theory and implementation of GPS systems can be found in Leick's book [29.25]. See also [29.26]. Details of various approaches to GPS/INS integration can be found in [29.27] and [29.28].

29.8 Currently Available Hardware

Although the specific models listed below are likely to have a short shelf life, the list of contacts is may be a good starting point for the identification of specific inertial sensing devices.

29.8.1 Gyroscopic Systems

- KVN DSP-3000 Tactical Grade Fiber Optic Gyro (FOG), KVH Industries Inc., 50 Enterprise Center, Meddletown RI, 02842-5279, USA, 1-401-847-3327
- Fiber Optic Gyroscope HOFG-1(A), Corporate Headquarters Hitachi Cable Ltd. 4-14-1 Sotokanda, Chiyoda-ku, Tokyo 101-8971, Japan.

- Rate Gyroscope CRS03, Silicon Sensing Systems Japan, Ltd. 1-10 Fusocho (Sumitomo Precision Complex), Amagasaki, Hyogo 660-0891, Japan.

29.8.2 Accelerometers

- Accelerometer GSA 101, A-KAST Measurements and Control Ltd., 1054-2 Centre St. Suite #299, Thornhill, ON, L4J 8E5, Canada.
- ENDEVCO MODEL 22, Brüel and Kjaer, DK-2850 Naerum, Denmark.

29.8.3 IMU Packages

- μ IMU, MEMSense, 2693D Commerce Rd., Rapid City, SD 57702, USA.
- IMU400 MEMS Inertial Measurement Unit, Crossbow Technology Inc., 4145 N. First St., San Jose, CA 95134, USA.
- IntertiaCube3, (3DOF IMU), Intersense, 36 Crosby Dr, #15, Bedford, MA 01730, USA.

29.8.4 GPS Components

- Garmin GPS 18, Garmin International Inc., 1200 East 151st St., Olathe, KS 66062-3426, USA.
- Magellan Meridian Color, Thales Navigation 471 El Camino Real, Santa Clara, CA 95050-4300, USA.
- TomTom Bluetooth GPS Receiver, Rembrandtplein 35, 1017 CT Amsterdam, The Netherlands.

30. Sonar Sensing

Lindsay Kleeman, Roman Kuc

Sonar or ultrasonic sensing uses the propagation of acoustic energy at higher frequencies than normal hearing to extract information from the environment. This chapter presents the fundamentals and physics of sonar sensing for object localization, landmark measurement and classification in robotics applications. The source of sonar artifacts is explained and how they can be dealt with. Different ultrasonic transducer technologies are outlined with their main characteristics highlighted.

Sonar systems are described that range in sophistication from low-cost threshold-based ranging modules to multitransducer multipulse configurations with associated signal processing requirements capable of accurate range and bearing measurement, interference rejection, motion compensation, and target classification. Continuous-transmission frequency-modulated (CTFM) systems are introduced and their ability to improve target sensitivity in the presence of noise is discussed. Various sonar ring designs that provide rapid surrounding environmental coverage are described in conjunction with mapping results. Finally the chapter ends with a discussion of biomimetic sonar, which draws inspiration from animals such as bats and dolphins.

30.1 Sonar Principles

Sonar is a popular sensor in robotics that employs acoustic pulses and their echoes to measure the range to an object. Since the sound speed is usually known, the object range is proportional to the echo travel time.

Fig.30.1a–d Sonar ranging principles: (a) sonar configuration, (b) echo waveform, (c) range dot placement, (d) sonar map

Fig.30.2a–c False range reading: (a) sonar configuration, (b) probing pulse 2 transmitted before echo from pulse 1 arrives, (c) false range (FR) is measured from transmission time 2

At ultrasonic frequencies the sonar energy is concentrated in a beam, providing directional information in addition to range. Its popularity is due to its low cost, light weight, low power consumption, and low computational effort, compared to other ranging sensors. In some applications, such as in underwater and low-visibility environments, sonar is often the only viable sensing modality.

Sonars in robotics have three different, but related, purposes:

1. **Obstacle avoidance:** the first detected echo is assumed to measure the range to the closest object. Robots use this information to plan paths around obstacles and to prevent collisions.
2. **Sonar mapping:** a collection of echoes acquired by performing a rotational scan or from a sonar array is used to construct a map of the environment. Similar to a radar display, a range dot is placed at the detected range along the probing pulse direction.
3. **Object recognition:** a sequence of echoes or sonar maps is processed to classify echo-producing structures composed of one or more physical objects. When successful, this information is useful for robot registration or landmark navigation.

Figure 30.1 shows a simplified sonar system, from its configuration to the resulting sonar map. A sonar transducer, T/R, acts as both the transmitter (T) of a probing acoustic pulse (P) and the receiver of echoes (E). An object O lying within the sonar beam, indicated by the shaded region, reflects the probing pulse. A part of the reflected signal impinges on the transducer as is detected as an echo. The echo travel time t_o , commonly called the *time-of-flight* (TOF) is measured from the probing pulse transmission time. In this case the echo waveform is a replica of the probing pulse, which usually consists of as many as 16 cycles at the resonant frequency of the transducer. The object range r_o is computed from t_o using

$$r_o = \frac{ct_o}{2}, \quad (30.1)$$

where c is the sound speed (343 m/s at standard temperature and pressure). The factor of 2 converts the round-trip ($P + E$) travel distance to a range measurement. Beam-spreading losses and acoustic absorption limit sonar range.

In forming a sonar map, a range dot is placed along the direction corresponding to the transducer's physical orientation. A sonar map is usually built by rotating the sensor about the vertical axis, indicated by the orientation angle θ , through a series of discrete angles

separated by $\Delta\theta$ and placing sonar dots the corresponding ranges. Since the range from the object O to the center of T/R is almost constant as T/R rotates, the range dots typically fall on a circle as long as O lies within the beam. Hence, sonar maps are made up of arcs.

The major limitations of sonar include:

1. The wide sonar beam causes poor directional resolution. Objects are located at the middle of isolated arcs, but shorter-range objects shorten the arcs of those at farther ranges, and the arcs produced by a collection of objects are often difficult to interpret. A consequence of this effect is that wide beams occlude small openings, limiting robot navigation.
2. The slow sound speed, relative to an optical sensor, reduces the sonar sensing rate. A new probing pulse should be transmitted after all detectable echoes from the previous pulse have expired, otherwise the false reading shown in Fig. 30.2 can occur. The echo from probing pulse 1 occurs after probing pulse 2 is emitted. Sonar measures the TOF from the most recent probing pulse. Many sonars transmit probing pulses every 50 ms, but encounter false readings in reverberant environments.
3. Smooth surfaces at oblique incidence do not produce detectable echoes. Figure 30.3 shows a planar surface (a wall) that acts as a mirror to the sonar beam. The important point is that the nearby wall does not itself produce a detectable echo, and a robot using sonar for obstacle avoidance may collide with the wall.
4. Artifacts caused by beam side-lobes and multiple reflections produce range readings in the environment where no objects exist. Figure 30.3 also shows the redirected beam enclosing object O. The echo is also redirected by the wall back to the transducer. From the transducer's reference, the object is at the virtual object location VO, and it would generate the same sonar map as shown in Fig. 30.1. Since there is no physical object corresponding to the sonar dot location, it is an artifact. Also, note that the acoustic energy indicated by the dot-dashed line reflected back to the transducer is not detected because it does not lie within the beam cone. Beam side-lobes often detect these echoes and produce shorter-range readings but placed along the sonar orientation.
5. Travel time and amplitude variations in the echoes caused by inhomogeneities in the sound speed. Both effects cause random fluctuations in the detected echo travel time, even in static environments. Fig-

Fig. 30.3 The smooth surface redirects the beam, causing a sonar artifact at virtual object (VO) location. The dot-dashed echo path falls outside the sonar beam and does not produce a detectable echo

Fig.30.4a,b Random echo jitter. (a) Sonar configuration; thermal inhomogeneities in the acoustic transmission medium cause refraction effects. (b) Examples of variations in echo travel times and amplitudes in a static environment

ure 30.4 illustrates thermal fluctuations that cause speed up, retardation, and travel redirection by refraction of echoes. These cause temporal and amplitude variations in the echoes and jitter in the range readings. While these typically introduce minor changes in sonar maps, they often cause havoc with approaches using finer analysis.

This chapter describes the physical and mathematical details that extend this simplified sonar model to practical sonar systems.

30.2 Sonar Beam Pattern

To derive a qualitative description of the sonar transducer, we apply elementary acoustics theory to a simplified model to achieve a simple analytic form [30.1]. A sonar emitter is commonly modeled as a circular piston surface of radius a vibrating with frequency f in an infinite planar baffle. The wavelength λ is

$$\lambda = \frac{c}{f}, \quad (30.2)$$

where c the sound speed in air, 343 m/s at 25 °C [30.2]. When $a > \lambda$ the emitted pressure field forms a beam consisting of a main lobe surrounded by side-lobes. In the far field, or range greater than a^2/λ , the beam is described by its *directivity pattern*, which is the two-dimensional Fourier transform of the aperture function, in this case the circular aperture produces a Bessel function. The emitted pressure amplitude at range r and angle θ relative to the piston axis can be written as

$$P_E(r, \theta) = \frac{\alpha a^2 f}{r} \left(\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right), \quad (30.3)$$

where α is a proportionality constant that includes the density of air and the source strength, $k = 2\pi/\lambda$, and J_1 is the Bessel function of the first kind. The term in the brackets evaluates to 1 along the sonar axis, $\theta = 0$. The a^2 term indicates that the emitted pressure increases with the piston area. The frequency f appears in the numerator because the faster-moving piston generates higher pressures. The range r appears in the denominator because the conservation of energy requires the pressure to decrease as the beam widens with range.

The main lobe is defined by its first off-axis null, which occurs at an angle of

$$\theta_0 = \arcsin \left(\frac{0.61\lambda}{a} \right). \quad (30.4)$$

For example, the popular electrostatic instrument grade transducer, formerly produced by Polaroid [30.3], had a radius of $a = 1.8$ cm and is conventionally driven at $f = 49.4$ kHz, making $\lambda = 0.7$ cm and $\theta_0 = 14.7^\circ$.

An object that is small compared to λ and located in the emitted pressure field produces an echo with a spherical wavefront whose amplitude decays with the inverse of the distance propagated. In the common pulse-echo single transducer (*monostatic*) ranging sensor, only part of the echo wavefront impinges on the receiving aperture. The *sensitivity pattern* of the circular aperture, now acting as the receiver, has the same beam-like Bessel function form given in (30.3) by the

reciprocity theorem [30.1]. If the reflecting object is located at (r, θ) relative to the transducer, the detected echo pressure amplitude, referenced to the receiver output, is given by

$$P_D(r, \theta) = \frac{\beta f a^4}{r^2} \left(\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right)^2, \quad (30.5)$$

where β is a proportionality constant that includes parameters that cannot be controlled in a design, such as the density of air. The additional a^2 in the numerator occurs because larger apertures detect more of the echo wavefront.

Figure 30.5 shows the echo amplitude from a small (point-like) object located in the far field as a function

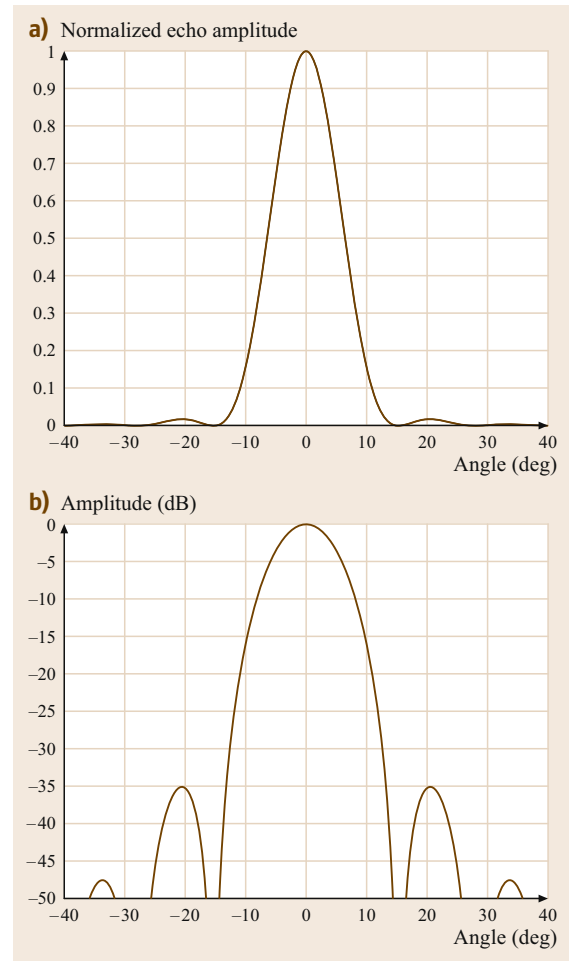

Fig. 30.5a,b Normalized amplitude of echo from small object predicted by the piston model as a function of angle. (a) Linear scale. (b) Decibel scale

of angle detected by the electrostatic instrument grade transducer. The curve has been normalized by the on-axis echo amplitude.

This model is qualitative in that it provides the following practically useful insights:

- For a small reflector size relative to the wavelength, the echo amplitude decreases inversely with the square of the range because there is a $1/r$ dispersion loss from the transmitter to the object, followed by an additional $1/r$ dispersion loss in the echo back to the receiver. However, larger reflectors can be treated using a Huygens principle approach [30.4] by dividing them into smaller reflectors and coherently adding their echo contributions. When this is done in two dimensions over a normally incident extended plane reflector, the echo amplitude decreases as $1/r$ rather than $1/r^2$. A cylindrical reflector extends over one dimension and results in an amplitude variation with range between $1/r$ and $1/r^2$. A more-extreme situation can occur with a concave reflector that acts as an acoustic magnifier, resulting in an amplitude that decreases with a negative power of range of less than one.
- The transducer excited by an approximation to a sinusoid exhibits side-lobes due to null caused by phase cancellation. For example, the 16-cycle excitation employed in the conventional sonar exhibits side-lobes. The peak of the first side-lobe is -35 dB relative to the echo amplitude when a small reflector lies on the transducer axis. The specification sheet for the 600 series instrument-grade transducer shows the first off-axis null at 15° and a first side-lobe peak magnitude of -26 dB. We presume that these measurements were made using a plane as a reflector.
- This model can be used to compute approximate beam parameter values for other common transducers. For example, the SensComp 7000 Series [30.5] with $a = 1.25$ cm yields $\theta = 20^\circ$, equal to the specified value. However, the specified first side-lobe peak magnitude equals approximately -16 dB, which is substantially different from the expected -35 dB.

The limitations of the qualitative model include:

- Actual transducers only approximate pistons vibrating in an infinite planar baffle. The infinite baffle directs all the radiated sound pressure into the half-space in front of the transducer. Actual transducers radiate in all directions, but most of the acoustic energy is concentrated within the main lobe.
- All pulse-echo ranging sonars operate with finite-duration pulses rather than infinite-duration sinusoids. Several systems described below use pulses that are quite different from a sinusoidal excitation, either in duration or in form. These are commonly analyzed by computing the spectrum of the pulse and decomposing it into several sinusoidal frequencies, each having its own beam pattern. For example, the echo amplitude predictions above are reasonably accurate, including beam width and side-lobes, for the 16-cycle pulses. However, when impulse or swept-frequency excitations are used, the net beam profile becomes the superposition (of linear amplitudes) of the beam patterns produced by each frequency component in the excitation. Such broadband excitations do not exhibit nulls because the nulls formed by one frequency are filled in by main and side-lobes of beams produced by other frequencies.
- Most sonar transducers are encased in protective housings. The electrostatic instrument-grade transducer cover forms a mechanical filter that enhances the acoustic output at 49.4 kHz. The cases of other transducers may distort the transmitted field, but most form some type of directional beam.
- The model does not include frequency-dependent acoustic absorption of the transmission medium. These reduce the echo amplitudes predicted by the model.

The analytic model above is limited to simple configurations. With current computational power, transducers can be extended to those with arbitrary, even multiple, apertures and with various excitations. Waveforms of echoes from objects having arbitrary shapes can be simulated by using Huygens principle [30.4]. The transmitter, receiver, and object surfaces are broken up into two-dimensional (2-D) surface arrays of emitting, reflecting, and detecting elements, using squares of dimension $< \lambda/5$ (the smaller the better, but taking longer). The impulse response of a given configuration is computed by assuming an impulsive emission and superimposing the travel times along all possible paths from all transmitter elements to all object elements and then to all receiver elements. The temporal resolution should be $< (20f_{\max})^{-1}$, where f_{\max} is the maximum frequency in the excitation. A 1- μ s resolution is adequate for a 16-cycle 49.4 kHz excitation. A much finer resolution (< 0.1 μ s) is required for an impulsive excitation. The echo waveform is then computed as the convolution of this impulse response with the actual transmitted pulse waveform [30.4].

30.3 Speed of Sound

The speed of sound c varies significantly with atmospheric temperature, pressure, and humidity and can be critical in determining the accuracy of a sonar system. This section outlines the relationship between c and these variables and is based on [30.6, 7].

The speed of sound in dry air at sea-level air density and one atmosphere pressure is given by

$$c_T = 20.05 \sqrt{T_C + 273.16} \text{ ms}^{-1}, \quad (30.6)$$

where T_C is the temperature in degrees Celsius. Under most conditions (30.6) is accurate to within 1%. However, should the relative humidity be known, a better estimate can be made as

$$c_H = c_T + h_r [1.0059 \times 10^{-3} + 1.7776 \times 10^{-7} (T_C + 17.78)^3] \text{ ms}^{-1}. \quad (30.7)$$

Equation (30.7) is accurate to within 0.1% for temperatures in the range -30 to 43°C for most pressures at sea level. Should atmospheric pressure, p_s be known then

the following expression can be used

$$c_P = 20.05 \sqrt{\frac{T_C + 273.16}{1 - 3.79 \times 10^{-3} \left(\frac{h_r p_{\text{sat}}}{p_s} \right)}} \text{ ms}^{-1}, \quad (30.8)$$

where the saturation pressure of air, p_{sat} is dependent on temperature as follows

$$\begin{aligned} \log_{10} \left(\frac{p_{\text{sat}}}{p_{s0}} \right) &= 10.796 \left[1 - \left(\frac{T_{01}}{T} \right) \right] - 5.0281 \log_{10} \left(\frac{T_{01}}{T} \right) \\ &\quad + 1.5047 \times 10^{-4} \left(1 - 10^{-8.2927 \left[\left(\frac{T}{T_{01}} \right) - 1 \right]} \right) \\ &\quad + 0.42873 \times 10^{-3} \left(-1 + 10^{4.7696 \left[1 - \left(\frac{T_{01}}{T} \right) \right]} \right) \\ &\quad - 2.2196, \end{aligned} \quad (30.9)$$

p_{s0} is the reference atmospheric pressure of 101.325 kPa and T_{01} is the triple-point isotherm temperature with the exact value of 273.16 K.

30.4 Waveforms

Sonars employ a variety of waveforms, the most common types of which are shown in Fig. 30.6. Each waveform can be considered the echo from a normally incident plane. Waveforms are classified as being narrow- or wide-band depending on their spectral bandwidth. Narrow-band pulses provide superior detection performance in the presence of additive noise, while wide-band pulses provide better range resolution and do not have side-lobes.

Figure 30.6a shows the waveform produced by the Murata 40 kHz piezoelectric transducer excited by an eight-cycle 40 kHz square wave 40 V_{rms}. The Murata sensor is small, lightweight, and efficient, but has an approximately 90° beam width. These transducers are used in monostatic, bistatic, and multiple transducer arrays [30.8, 9].

The next three waveforms were produced by the Polaroid 600 electrostatic transducer. Similar waveforms are generated by the smaller Polaroid 7000 transducer. Figure 30.6b shows the waveform produced by the 6500 ranging module. This ranging module with its 10 m range, low cost, and simple digital interface is

a popular choice for implementing sonar arrays and rings. While the electrostatic transducer is inherently wide-band, with a usable frequency range from 10 to 120 kHz [30.10], narrow-band pulses are produced by exciting the transducer with 16 cycles at 49.4 kHz. Figure 30.6c illustrates a means to exploit the wide bandwidth of the Polaroid electrostatic transducer by exciting it with a decreasing-frequency square wave. Such frequency-sweep pulses are processed by a band of band-pass filters to extract the frequency dependence of reflecting objects. A correlation detector, also known as a matched filter, compresses swept-frequency pulses to improve range resolution. Longer-duration (100 ms) pulses are used in CTFM systems. Figure 30.6d shows a wide-band pulse when the excitation is a 10 μs -duration 300 V pulse. The metal protective mesh, which also acts as a mechanical filter resonant at 50 kHz, was removed by machining to achieve a usable bandwidth from 10 to 120 kHz, with the peak occurring at 60 kHz. Such wide-band pulses are useful for object classification [30.10, 11]. These pulses have small amplitudes, limiting their range to 1 m or less.

Fig.30.6a–d Common sonar pulse waveforms. **(a)** Murata 40 kHz transducer (narrow band). **(b)** Polaroid 600 electrostatic transducer excited with 16-cycle sinusoid at 49.4 kHz (6500 ranging module – narrow band). **(c)** Polaroid 600 electrostatic transducer excited with decreasing-frequency excitation signal (wide band). **(d)** Polaroid 600 electrostatic transducer excited with 10 μ s 300 V pulse (wide band)

30.5 Transducer Technologies

Electrostatic and piezoelectric transducers are the two major types available that operate in air and can in principle operate both as a transmitter and receiver – some samples are shown in Fig. 30.7. In general electrostatic devices have a higher sensitivity and bandwidth but typically require a bias voltage above 100 V. Piezoelectric devices operate at lower voltages, making their electronic interfacing simpler, but have a high- Q resonant ceramic crystal and this results in a narrow frequency response compared to electrostatic transducers.

30.5.1 Electrostatic

An example of an electrostatic transducer is the Polaroid instrument-grade transducer (now available from SensComp.com) constructed from a gold-coated plastic foil membrane stretched across a round grooved aluminium back plate. The conductive foil is charged via a bias voltage of 150 V with respect to the back plate. Incoming sound waves vibrate the foil and change the average distance between the foil and back plate and thereby changing the capacitance of the foil. Assum-

ing that the charge q is constant, the voltage $v(t)$ is generated proportional to this varying capacitance $C(t)$ as $v(t) = qC(t)$. As a transmitter, the transducer membrane is vibrated by applying 0–300 V pulses across this capacitor, typically using a pulse transformer. The

Fig. 30.7 Left to right: Series 9000, instrument-grade, and Series 7000 transducers; front and back views are shown (courtesy Acroname, Inc., Boulder)

charge induced by the 300 V on the capacitor causes an electrostatic attraction force between the membrane and the back plate. The grooves on the back plate allow stretching of the membrane and by creating randomness in the back plate roughness a broad resonance can be achieved in the frequency response. For example the bandwidth of the 7000 series Polaroid transducer is 20 kHz. A front grille is mounted on the transducer and removing this grille reduces losses and reverberation between the grille and the membrane. Another electrostatic transducer was designed by Kay and details of its design can be found in [30.12].

30.5.2 Piezoelectric

Piezoelectric ceramic transducers can be used as both transmitters and receivers, however some manufacturers sell transmitters and receivers separately in order to optimize the transmitted power and receiver sensitivity, respectively. A piezoelectric resonant crystal mechanically vibrates when a voltage is applied across the crystal, and in reverse generates a voltage when mechanically vibrated. Often a conical concave horn is mounted on the crystal to acoustically match the crystal acoustic impedance to that of air. An example is the Murata MA40A5R/S receiver and sender transducers, which operate at 40 kHz. This device has a diameter of 16 mm and a 60° beam angle for transmitter combined with receiver for -20 dB loss compared to the maximum sensitivity. The effective bandwidth of transmitter and receiver is only a few kHz due to the resonant na-

ture of the crystals. This limits the envelope rise time of pulses to around 0.5 ms. An advantage is the ability to drive piezoelectric devices with low voltages, for example by connecting each terminal to complementary CMOS logic outputs. There is a wide range of resonant frequencies for piezoelectric transducers from 20 kHz to megahertz. Also available is piezoelectric film called polarized fluoropolymer, polyvinylidene fluoride (PVDF) from [30.13]. This flexible film can be cut to shape and custom ultrasonic transmitters and receivers can be formed. The sensitivities of the transmitters and receivers made from PVDF is generally lower than that of ceramic crystal transducers and most applications are short range where the broadband nature of PVDF allows short pulses to be formed, allowing pulse-echo ranging to as little as 30 mm.

30.5.3 MEMS

Microelectromechanical system (MEMS) ultrasonic transducers can be fabricated on a silicon chip and integrated with electronics. The sensors offer a low-cost mass-produced alternative to standard transducers. MEMS ultrasonic transducers operate as electrostatic capacitive transducers where the membrane can be made from thin nitride. Devices operate at frequencies up to several megahertz and offer advantages in signal-to-noise ratio over piezoelectric devices due to their better matching to air acoustic impedance [30.14]. Two-dimensional arrays of devices can be deployed on a chip that are well matched and steerable.

30.6 Reflecting Object Models

Modeling the reflection processes helps in interpreting echo information. In this section we consider three simple reflector models: planes, corners, and edges, shown in Fig. 30.8. These models apply to both single transducers and arrays.

A plane is a smooth surface that acts as an acoustic mirror. Smooth walls and door surfaces act as planar reflectors. The plane must be sufficiently wide to produce the two reflections whose path is shown in dotted line. The plane reflector is then slightly larger than the intersection area of the beam with a plane of infinite extent. Smaller planes produce weaker echoes because of a smaller reflecting surface and negative interference by echoes diffracted from the edges of the plane. An acoustic mirror allows the analysis using a virtual transducer, indicated by primes in the figure.

A corner is the concave right-angle intersection of two surfaces. Corners formed by intersecting walls, the

sides of file cabinets, and door jambs are commonly observed corner reflectors in indoor environments. The novel feature of the corner, and its three-dimensional (3-D) counterpart the corner cube, is that waves reflect back in the same direction from which they originate. This is caused by planar reflections at each of the two surfaces defining the corner. The virtual transducer is then obtained by reflecting the transducer about one plane of the corner and then the other plane. This gives rise to a reflection through the intersection point of the corner as shown in Fig. 30.8b. The virtual transducer analysis indicates that, for a monostatic sonar, echoes from a plane and corner are identical and that planes and corners can generate identical sonar maps [30.4]. The difference in the virtual transducer orientation between planes and corners has been exploited using transducer arrays to differentiate these reflectors [30.11, 15].

Fig. 30.8a–c Reflector models: (a) plane, (b) corner, and (c) edge

Fig. 30.9 Random reflector model. Echoes reflect back from normally incident surface sections within the beam

The edge shown in Fig. 30.8c models physical objects such as convex corners and high-curvature surfaces (posts), where the point of reflection is approximately independent of transducer position. Edges are encountered in hallways. While planes and corners generate strong echoes, edges generate weak echoes that are detected only a short range [30.4], making them difficult objects to detect. Early robot sonar researchers placed bubble wrap material on edge surfaces to make them reliably detectable.

Many environmental objects can be configured as a collection of planes, corners, and edges. Models for echo production [30.16, 17] indicate that normally incident surface patches and locations at which sharp changes in the surface function and its derivatives generate echoes. Objects with rough surfaces or a collection of many objects generate echoes from a variety of ranges and bearings, as illustrated in Fig. 30.9. If $p(t)$ represents a single echo waveform, often a replica of the probing waveform, the total echo waveform $p_T(t)$ is the sum of individual echoes $p_i(t)$ from N normally incident patches at range r_i and bearing θ_i , scaled by amplitude a_i , or

$$p_T(t) = \sum_{i=1}^N a_i(\theta_i) p_i\left(t - \frac{2r_i}{c}\right), \quad (30.10)$$

where $a_i(\theta_i)$ is an amplitude factor related to the surface patch size and its bearing in the beam. Wide-bandwidth echoes are more complicated because their waveform changes in a deterministic fashion due to diffraction [30.11].

Sonars that analyze $p_T(t)$ employ analog-to-digital converters to obtain waveform samples [30.11, 18]. Reflecting patches separated in range produce isolated patches [30.11], but more often the incremental travel time is less than the pulse duration, causing pulse overlap. Rough surfaces and volume scatterers, such as indoor foliage, have large N , allowing $p_T(t)$ to be treated as a random process [30.19, 20]. Conventional TOF sonars output the first time that $p_T(t)$ exceeds a threshold [30.11].

30.7 Artifacts

Sonars usually work well in simple environments, while complex environments often produce mysterious readings, artifacts, that foil attempts to build reliable sonar maps. Artifacts have given sonar a bad reputation as being a noisy, or low-quality, sensing modality. Sonar stalwarts believe sonar would open up many new appli-

cations, *if only* we understood echoes at a level that approximates that employed by bats and dolphins [30.21]. Sonar stalwarts divide into two categories in terms of how they treat artifacts. The first attempts to build *intelligent sensors* that identify and suppresses artifacts before transmitting data to a higher-level reasoning pro-

gram. Previous approaches [30.22, 23] required custom electronics, which other researchers have been reluctant to adopt because of expense or lack of experience. An alternate approach is to control conventional sonar in a novel fashion to produce a series of spikes and requires only software changes [30.24]. Sonar arrays have been used to find consistent data [30.25–27]. Echoes from specular reflectors, such as planes, corners, or posts, exhibit detectable features, which can be obscured by artifacts.

The second category of sonar users attempts to eliminate artifacts produced by conventional sensors by using higher-level postprocessing. These include proponents of occupancy (or certainty) grids [30.28, 29], including those that apply simplified physical models, such as sonar arcs [30.30, 31]. In simple environments postprocessing usually eliminates artifacts that are inconsistent with a feature [30.32] or with a physical map [30.31]. More-sophisticated methods handle artifacts by treating them as noise and applying hidden Markov models (HMM) [30.33]. However, multiple passes are needed to successfully teach the system about relatively simple environments, mostly because artifacts are not amenable to being treated as independent additive noise. Eliminating troublesome artifacts would replace HMM with simpler Markov chains [30.34, 35], and sufficient sonar data can be obtained in a single pass. What frustrates this second category, and mildly amuses the first, is that this postprocessing works well in *simple environments*, but fails in real-world environments. This second category eventually abandons sonar and joins the camera and laser ranging crowd.

There are two important classes of artifacts: axial multiple reflection (MR) artifacts and dynamic artifacts. These artifacts are important in sonar mapping when they indicate the presence of a static object at a location where none exists. Troublesome MR artifacts are caused by delayed echoes produced by a previous probing pulse exceeding the detection threshold after the current probing pulse has been transmitted. Such artifacts then appear as close-range objects and

obscure actual farther-range objects in conventional sonars. Most sonars employ probing pulse emission periods longer than 50 ms to avoid MR artifacts, although some reverberant environments can still produce artifacts [30.36].

Dynamic artifacts are produced by moving objects, such as individuals passing through the sonar beam. Even though these are actual objects and echoes indicate their true range, their presence should not be part of a sonar map that describes the static environment. Such dynamic artifacts make quantitative matchings between stored and generated sonar maps error-prone.

Another common artifact is a nonaxial MR artifact [30.4] caused by an obliquely incident smooth surface that redirects the sonar beam to some other echo-producing object. The TOF produces a range reading that is positioned along the sonar axis. While the object is not at the location indicated on a sonar map, its location in the sonar map is a stable element and can be useful for navigation.

One may argue that, if the locations of all objects are known, the echoes can be determined and should not be treated as random processes. However, the presence of speed fluctuations in the medium due to thermal gradients and ever-present electronic noise cause random fluctuations in the times that thresholds are exceeded. Even a stationary sonar in a static environment exhibits random fluctuations [30.37], similar to the visual experience of fading when viewing objects beyond a heated surface.

Sonar can identify artifacts by applying three physical criteria that are met by echoes from static environmental objects. Artifact features include [30.36]:

1. Echo amplitude – echoes with amplitudes less than a specified threshold
2. Coherence – echoes forming constant-range azimuthal intervals less than a specified threshold, and
3. Coincidence – echoes detected with a sonar array at different times (lacking temporal coherence) or corresponding to different locations (lacking spatial coherence).

30.8 TOF Ranging

Most conventional sonars employ Polaroid 6500 ranging modules [30.38] connected to the Polaroid 600 series electrostatic ultrasound transducer. The module is controlled with digital signals on two input lines (*INIT* for initialization and probing pulse transmission and *BLNK* for clearing the indication and resetting the detector) and the TOF reading occurs on its output line

(*ECHO*). A logic transition on *INIT* causes the transducer to emit a pulse lasting for 16 cycles at 49.4 kHz. The same transducer detects echoes after a short delay to allow transmission transients to decay. Another interrogation pulse is typically emitted only after all the echoes produced by the previous pulse have decayed below a detection threshold.

The module processes echoes by performing rectification and lossy integration. Figure 30.10 illustrates a simulation of the processed waveform applied to the threshold detector. While the echo arrives at time t_0 after the emission, *ECHO* exhibits a transition at the measured TOF time t_m , the first time the processed echo signal exceeds a detection threshold τ . By convention, the range r of the reflecting object is calculated by

$$r = \frac{ct_m}{2}, \quad (30.11)$$

where c is the speed of sound in air, usually taken as 343 m/s.

Figure 30.10b shows details around the threshold detection point including the residual high-frequency ripple after full-wave rectification and integration. Two effects can be noticed. First, t_m will always occur after t_0 , making threshold detection a biased estimate of the true echo arrival time. Moreover, this bias is related to the echo amplitude: stronger echoes will produce an integrator output having a greater slope, which exceeds τ sooner than t_m . Second, as the echo amplitude decreases, for example, when the object moves away from the transducer axis, the threshold level occurs later in the integrator output and t_m will experience small jumps in time approximately equal to half the period [30.39].

The first step in developing a model of the detection process is to develop a model for the echo amplitude as a function of bearing. The Polaroid transducer is often modeled as a vibrating piston to yield the transmitter/receiver beam pattern shown in Fig. 30.11. To simplify the analysis, the peak of the beam profile is

approximated with a Gaussian function, a parabola in logarithmic units in Fig. 30.11, to determine the echo amplitude as a function of object bearing θ , or

$$A_\theta = A_0 \exp\left(-\frac{\theta^2}{2\sigma^2}\right), \quad (30.12)$$

where A_0 is the on-axis amplitude and σ is a measure of the beam width. The value $\sigma = 5.25^\circ$ provides a good fit around the peak of the beam pattern. The Gaussian model is reasonable only over the central section of the main lobe that produces detectable echoes.

We assume that the echo arrival time t_0 does not change significantly with transducer orientation (object bearing); this effect was investigated and found to be minor [30.4]. In contrast, measured TOFs, denoted by t_m and t'_m in Fig. 30.12, are amplitude dependent and a function of object bearing, which affects echo amplitude as shown in Fig. 30.11.

The module processes the detected echo waveform by rectification and lossy integration, as discussed above. To derive a useful analytic model, assume that the integration is lossless and the rectified echo is a unit step function with amplitude A . This approximates the processed waveform shown in Fig. 30.10b by a linear function around time t_m , shown in Fig. 30.12. The model ignores the residual ripple and the decreasing slope of the waveform as the lossy rectification approaches a constant value, shown in Fig. 30.10. The linear function with a slope proportional to the echo amplitude is given by $A_\theta(t - t_0)$, for $t \geq t_0$. This function

Fig. 30.13a–c TOF data from an object at 1.5 m range; mean of 100 measurements with bars indicating ± 1 SD. The *dashed lines* are model predictions. **(a)** 1 m wide plane ($\tau/A = 0.15 \mu\text{s}$). **(b)** 8.9 cm diam pole ($\tau/A = 0.67 \mu\text{s}$). **(c)** 8 mm diam rod ($\tau/A = 2.68 \mu\text{s}$) ►

exceeds the threshold τ at

$$t_m = t_0 + \frac{\tau}{A_\theta} = t_0 + \frac{\tau}{A_0} \exp\left(\frac{\theta^2}{2\sigma^2}\right). \quad (30.13)$$

For fixed τ , the incremental delay in t_m is a function of the bearing θ and inversely proportional to the echo amplitude. When a constant echo amplitude A (in volts) is applied to the integrator, the slope of the linear output is A V/s, with typical values on the order of $A_\theta = 10^5$ V/s. If $\tau = 0.10$ V, $\tau/A_\theta = 10^{-6}$ s = $1 \mu\text{s}$.

Experiments were conducted with a Polaroid 600 series transducer connected to a model 6500 ranging module [30.39]. The Polaroid module was operated conventionally to generate t_m values as a rotational scan was performed. Objects include a 1 m-wide plane, a 8.9 cm-diameter pole, and an 8 mm-diameter rod, all located at 1.5 m range. A rotational scan was performed from -40° to $+40^\circ$ in 0.3° steps. At each angle, 100 t_m values were recorded. The mean deviations from the t_m when the object is on the sonar axis ($\theta = 0$) were determined and the standard deviation (SD) values were computed. There were no other objects in proximity to the object being scanned. Echoes from objects beyond 2 m were eliminated by a range gate.

Figure 30.13a shows the data for the plane, Fig. 30.13b for the pole, and Fig. 30.13c for the rod. The values are shown relative to the t_m value observed at 0° bearing. Dashed lines indicate the values predicted by the model. The t_m values showed a variation with $\text{SD} = 5 \mu\text{s}$ (0.9 mm) at zero bearing, which is about nine times greater than that predicted by sampling

jitter alone. This random time jitter is caused by dynamic thermal inhomogeneities in the air transmission medium, which change the local sound speed and cause refraction [30.37, 40]. The SD increases with deviation from zero bearing because smaller echoes exceed the threshold later in the processed waveform. The smaller

slope of the latter part of the processed echo waveform shown in Fig. 30.10 causes greater t_m differences for a given variation in echo amplitude, thus increasing the SD.

One feature in the data not described by the model is due to residual ripple in the integrator output, which causes jumps in TOF readings equal to half periods (10 μ s) added to the value predicted by (30.13). These jumps are clearly evident in the mean values of Fig. 30.13.

The angular extent over which echoes were detected was 45° for the plane, 22.8° for the pole, and 18.6° for the rod. Side-lobes produced by the plane are visible

and have small echo amplitudes, which cause their t_m values to be retarded in time. These angular extents can be related to the echo amplitudes that would have produced the respective arcs according to the piston model; these are indicated in Fig. 30.11. For the plane, the threshold level relative to the maximum echo amplitude is -38 dB, for the pole -25 dB, and for the rod -13 dB. Since the ranging module threshold at 1.5 m range is the same for each object, the difference in levels indicates the relative echo strength from each object, i. e., the plane echo is 13 dB (a factor of 4.5) greater than the pole echo, and the pole echo is 12 dB (a factor of 4) greater than the rod echo.

30.9 Echo Waveform Coding

Systems that display echo information beyond the first echo have been investigated [30.11, 18, 25, 41–43], but typically employ custom electronics. One motivation for examining the entire echo waveform is the success of diagnostic medical ultrasound imaging systems, which adopt this method [30.44, 45].

As a less expensive alternative to analog-to-digital conversion, the Polaroid ranging module can detect echoes beyond the initial echo by repeatedly resetting the detection circuit. The 6500 module specification suggests a delay before resetting to prevent the current echo from retriggering the detection circuit [30.3]. Let us ignore this suggestion and control the Polaroid module in nonstandard way to provide information about the entire echo waveform. Since the echo amplitude is estimated from the digital output produced by the Polaroid module, this operation has been called *pseudo-amplitude scan* (PAS) sonar [30.24].

The conventional ranging module processes detected echoes by performing rectification and forming a lossy integration, as illustrated in Fig. 30.14a.

The BLNK input is typically kept at zero logic level, which enables the ECHO output. ECHO exhibits a transition at the time when the processed echo signal exceeds a threshold, as shown in Fig. 30.14b. By convention, the time interval between the INIT and ECHO transitions indicates the time of flight (TOF), from which the range r of the reflecting object is calculated by

$$r = \frac{c \times \text{TOF}}{2} . \quad (30.14)$$

Echoes occurring after the initial echo can be detected by resetting ECHO by pulsing the BLNK input. The specification suggests that the BLNK pulse should be delayed after the ECHO indication by at least 440 μ s

to account for all 16 returning cycles in the echo and to allow it to decay below the threshold for the largest observable echo. The largest echoes typically saturate the detection circuit, providing a predetermined maximum value. This duration corresponds to the time interval over which the processed signal is above the threshold, as shown in Fig. 30.14a.

When an ECHO event is observed, the PAS system issues a short 3 μ s (corresponding to a software query period) pulse on the BLNK input line, which clears the ECHO signal as shown in Fig. 30.14c. Upon being cleared, the Polaroid module exhibits a delay inversely related to the echo amplitude, lasting at least 140 μ s for large-amplitude echoes, and then produces

Fig. 30.14a–c Polaroid ranging module operation modes. (a) Processed echo waveform. (b) ECHO output produced in conventional time-of-flight mode. (c) ECHO output produced in PAS mode

another *ECHO* event if the processed echo signal still exceeds the threshold. The *PAS* system repeatedly issues a *BLNK* pulse whenever an *ECHO* event is observed. Hence, a strong echo is represented by three pulses on the *ECHO* line, the first corresponding to the conventional *TOF*, followed by two more pulses. Because lower amplitude echoes spend less time above the threshold, a weaker echo produces two pulses spaced farther apart, and a very weak echo may produce only one pulse. Shorter *INIT* pulses discharge the integrator by a lesser amount and thus increase the number of pulses produced by the standard Polaroid emission [30.46, 47].

A *PAS* sonar map is generated by placing a range dot along the transducer axis as a rotational scan is executed. With multiple readings per interrogation pulse, a *PAS* sonar map contains multiple dots at each interrogation angle. Rotational scans then form arcs, with isolated arcs indicating weak echoes, arc pairs moderate echoes, and arc triplets large echoes. To illustrate, Fig. 30.15 shows arcs formed by a large plane (2.3 m width by 0.6 m height) and five cylinders with different diameters, all placed at 1 m range. Examining objects at the same range eliminates effects caused by the range-dependent gain of the module.

A conventional *TOF* sonar map by comparison would display only the nearest arc in the *PAS* map for each object. Qualitatively, the arc length increases and the number of arcs increase with the echo amplitude, which is bearing dependent. The strongest reflectors produce concave arcs [30.4, 48]. This occurs because, with echo amplitudes much greater than the threshold, the threshold is exceeded near the beginning of the echo, yielding a nearly constant range reading over a significant extent over bearing. In contrast, the weakest reflectors produce convex arcs, caused by echoes whose amplitudes are comparable to the threshold. As the echo amplitude decreases the threshold is exceeded at later points along the processed waveform, producing greater range readings. This effect also appears at the edges of the arcs produced by strong reflectors.

Fig. 30.15 *PAS* sonar maps of six objects located at 1 m range. The sonar is located below the objects in the figure

Computing the beam pattern of the vibrating piston model [30.1], which is a reasonable approximation to the Polaroid transducer, yields the curve shown in Fig. 30.16.

This figure describes the detected echo magnitude normalized to have a maximum of 0 dB, which occurs along the beam axis. The larger echoes are much greater than the threshold, such as those produced by the plane, whose maximum amplitudes can be 44 dB relative to the threshold. The -44 dB threshold agrees with the *PAS* map for a plane: strong echoes (three stripes) occur within 10° of normal incidence, range readings increase due to echo amplitude reduction at $\pm 15.6^\circ$, approximating the predicted nulls at $\pm 14.7^\circ$, and smaller-amplitude echoes from the side-lobes are present. Weaker reflectors correspond to larger thresholds when their on-axis echoes normalize to 0 dB. The beam pattern model explains how arc length varies with object reflecting strength. The indicated thresholds were found by matching the angular beam width to the arc extent.

It is apparent that *PAS* maps provide information useful for solving the inverse problem, that of determining the identity of the object from the echoes. Figure 30.15 shows that *PAS* maps contain information about the echo amplitude. While it is true that the conventional *TOF* sonar maps, represented by the closest arc, can determine the object location from the arc center and can infer the echo amplitude from the arc extent, it is also true that this information is presented in a more robust way in the *PAS* maps. For this simple case of isolated objects, the posts can be clearly differentiated from the pole, while the corresponding conventional *TOF* arcs are comparable. A tenfold in-

Fig. 30.16 Transmitter–receiver beam pattern. Dashed lines indicate the equivalent threshold level for each object

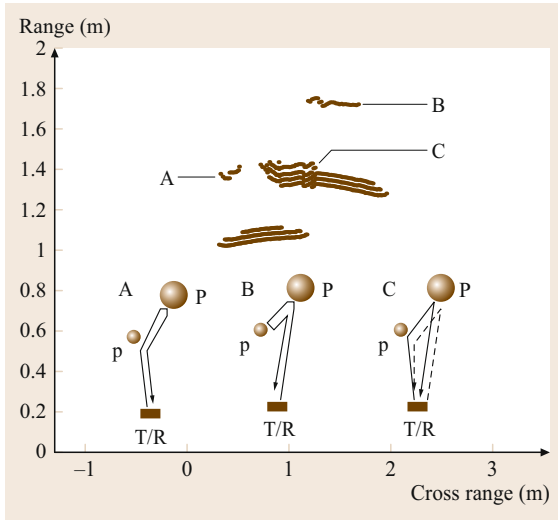

Fig. 30.17 PAS sonar map of 2.85 cm-diameter post (p) and 8.9 cm-diameter post (P). The transducer is located at (0,0). A: Artifact caused by echo originating at transmitter T, reflected by p, bouncing off P back to p, and directed toward receiver $T \rightarrow p \rightarrow P \rightarrow p \rightarrow R$. B: $T \rightarrow P \rightarrow p \rightarrow P \rightarrow R$. C: $T \rightarrow p \rightarrow P \rightarrow R$ and $T \rightarrow P \rightarrow p \rightarrow R$

crease in post diameter yields only a modest increase in the conventional TOF arc length, while increasing the number of arcs from two to three in the PAS maps. Spike data can be processed to produce sonar images of the environment that are similar to diagnostic ultrasound B-scans [30.49].  VIDEO 315 shows a sonar B-scan of a tree.

When examining the entire echo waveform, one must account for artifacts that are produced when ob-

jects interact acoustically. Some artifacts occur after the first detected echo, so these are not a problem in TOF sonar maps [30.4], but must be addressed in interpreting PAS maps. Consider a simple environment consisting of two posts: a 2.85 cm-diameter post (p), located at $r = 1$ m and bearing 12° , and an 8.9 cm-diameter post (P), at $r = 1.3$ m and bearing -10° . The corresponding PAS map shown in Fig. 30.17 displays the echoes from the two objects plus additional echoes that illustrate two types of multiple reflection artifacts.

The first type, indicated by A and B, results when only one object is within the transducer beam. An interrogation pulse that is redirected by a reflected object must be directed back to the receiver within its beam pattern in order to be detected. The paths that do this are shown in the figure. The single-arc convex shape of A indicates that the echo has a small amplitude. This is reasonable since both reflectors are nonplanar, and hence weak.

The second type of artifact (C) shown in Fig. 30.17 occurs when both objects are within the beam pattern. This allows two distinct paths for the echoes to return to the receiver, occurring in opposite directions and doubling the artifact amplitude. With both objects lying near the beam edges, the echo amplitude is small. Since the distance traveled by these echoes is slightly greater than the range to the farther object, this artifact shows a range slightly beyond the more distant object. The superposition of these two components makes the echo from the farther object appear spread out in time. This pulse stretching explains why four arcs are observed, and at one angle five arcs. If the bearing angle between p and P was increased to exceed the beam width, this artifact would disappear.

30.10 Echo Waveform Processing

In this section pulse-echo sonar that processes sampled digitized receiver waveforms is described. These systems offer superior performance over the simple Polaroid ranging module systems described above, which report the TOF based on a threshold. Echo waveform processing does however incur the overhead of more-complex electronics and signal processing and is not readily available commercially.

30.10.1 Ranging and Wide-Bandwidth Pulses

It is shown in [30.11, 50] that the maximum-likelihood estimator (MLE) for the TOF is obtained by maximizing the correlation $\text{cor}(\tau)$ between the received pulse $p(t)$ (containing Gaussian white noise) and the known

pulse shape shifted by τ , $\text{rec}(t - \tau)$

$$\text{cor}(\tau) = \frac{\int_a^b p(t) \text{rec}(t - \tau) dt}{\sqrt{\int_a^b p^2(t) dt \int_a^b \text{rec}^2(t) dt}}, \quad (30.15)$$

where the pulse extends from time a to b . The known pulse shape at the receiver depends on the angle of transmission and reception with respect to the normals of the respective transducers. The pulse shape can be obtained by collecting a good signal to noise pulse at 1 m range at normal incidence to the receiver and transmitter and using elliptical impulse response models to obtain template pulses at angles different to normal incidence. Pulse shape also changes with range due to the dispersive properties of absorption due losses in air

transmission. These can be modeled using an estimate of the impulse response due to one meter path through air as is done in [30.11].

The correlation, $\text{cor}(\tau)$ is normalized in (30.15) to be between -1 and $+1$. The correlation at the maximum thus gives a good indication of the match between

Fig. 30.18 Bearing (θ) calculation for a plane using a transceiver T/R1 and a receiver R2. T' is the virtual image of T

Fig. 30.19 Bearing (θ) calculation for a corner using a transceiver T/R1 and a receiver R2. T' is the virtual image of T

Fig. 30.20 Bearing (θ) calculation for an edge using a transceiver T/R1 and a receiver R2. No virtual image is present since the edge radiates from a point source at the edge

the expected and actual pulse shapes and can be used to assess the quality of the TOF estimate. In practice (30.15) is used in discrete time form, where the integrals are replaced by sums of products and digital signal processors are an ideal implementation since they are highly optimized to perform this calculation [30.51, 52]. Finding the maximum correlation of (30.15) is known as template matching. To achieve an arrival time estimator with resolution smaller than the discrete time sample rate, parabolic interpolation can be used on the maximum three correlations [30.11]. Of interest is the jitter standard deviation σ_R in the TOF estimator due to receiver noise. From [30.11, 50]

$$\sigma_R = \frac{\sigma_n}{B \sqrt{\sum_k \text{rec}(kT_s)^2}}, \quad (30.16)$$

where the summation index k is over the entire receiver pulse sampled every T_s seconds ($1 \mu\text{s}$ in [30.11, 51]), B is the bandwidth of the receiver pulse, and σ_n is the standard deviation of the receiver noise. Equation (30.16) shows that broadband high-energy pulses achieve low errors in the TOF estimator. In [30.11] this is achieved by using a 300 V pulse to excite the transmitter and achieve close to the impulse response from the device with a pulse shape similar to that shown in Fig. 30.6d.

30.10.2 Bearing Estimation

There are many proposed methods for bearing estimation. A single transducer [30.53] can be used by exploiting the dependency of the received pulse shape on the angle of reception. This approach works for angles within one half of the beam width since the pulse shape is symmetric with respect to the transducer normal angle. Differences in zero-crossing times either side of the maximum amplitude of the pulse are used to obtain an accuracy of the order of 1° . Other single-receiver techniques rely on repeated measurements from a scan across the scene [30.54, 55] and achieve a similar level of accuracy but at much slower sensing speed since multiple readings are necessary.

Other single measurement approaches rely on two or more receivers [30.11, 12, 25]. This gives rise to a correspondence problem where data must be associated between the receivers. The closer the spacing between receivers, the simpler and more reliable the correspondence procedure. The misconception that bearing accuracy improves with larger receiver spacing ignores the correlation between measurement errors that can arise due to the measurements sharing an overlapping space of air in the propagation of the ultrasound. Due to the high accuracy of TOF estimation in [30.11] the receivers could be spaced as close as physically feasible (35 mm) and still bearing accuracies lower than any

other systems are reported. Standard deviations of bearing errors are reported to be below 0.2° for a plane at a range of 4 m within a -10° to $+10^\circ$ beam width.

There are two common approaches to bearing estimation – interaural amplitude difference (IAD) [30.56] and interaural time difference (ITD) [30.11, 25, 51–53, 56]. IAD uses two receivers pointing away from each other so that an echo has a different amplitude response in each receiver's beam width. In ITD both receivers usually point in the same direction and the TOF is measured on each receiver and triangulation is applied to determine the angle of arrival. The bearing calculation is dependent on the target type, such as a plane, corner or edge; these geometries are analyzed in [30.11]. A simple arrangement with a transceiver and receiver is shown in Fig. 30.18, where T/R1 is the transceiver and R2 is the second receiver, spaced a distance d from each other.

The virtual image of the transmitter is shown as T'. The two TOFs measured on the two receivers are t_1 and t_2 , and these are used to estimate the bearing angle, θ , to the plane which is the angle to the plane normal. Applying the cosine rule to the triangle R2 R1 T' in Fig. 30.18 gives

$$\cos(90 - \theta) = \sin \theta = \frac{d^2 + c^2 t_1^2 - c^2 t_2^2}{2dc t_1}. \quad (30.17)$$

30.11 CTFM Sonar

The continuous-transmission frequency-modulated (CTFM) sonar differs from the more common pulse-echo sonar discussed in previous sections in the transmission coding and the processing required to extract information from the receiver signal.

30.11.1 CTFM Transmission Coding

The CTFM transmitter continuously emits a varying-frequency signal, usually based on a sawtooth pattern as shown in Fig. 30.21, where the frequency is often swept through an octave every sweep cycle T .

The transmitted signal with a linearly changing frequency can be expressed as

$$S(t) = \cos[2\pi(f_H t - bt^2)] \quad (30.20)$$

for $0 \leq t < T$. The sweep cycle is repeated every T seconds as shown in Fig. 30.21. Frequency is $1/2\pi$ times the time derivative of the phase in (30.20). Note that the highest frequency is f_H and the lowest transmitted frequency is $f_H - 2bT$, where b is a constant that determines the sweep rate. We can then define the swept

When $d \ll ct_1$, (30.17) can be approximated by

$$\sin \theta \approx \frac{c(t_1 - t_2)}{d}. \quad (30.18)$$

Note that any common (i. e., correlated) noise in t_1 and t_2 is removed by the difference in (30.18) and hence the correlation in noise components of the TOF cannot be overlooked in bearing estimation as described above.

The situation for a corner is shown in Fig. 30.19 and the same result applies as in (30.17).

For an edge the situation is shown in Fig. 30.20, where R1 has a TOF from T to the edge and back to R1, whilst R2 has a TOF from T to the edge and back to R2.

From the geometry, we use the same approach as in (30.17) to give

$$\begin{aligned} \sin \theta &= \frac{d^2 + \frac{c^2 t_1^2}{4} - c^2 \left(t_2 - \frac{t_1}{2}\right)^2}{2dc \frac{t_1}{2}} \\ &= \frac{d^2 + c^2 t_2(t_1 - t_2)}{dct_1}. \end{aligned} \quad (30.19)$$

Note that (30.19) can be approximated by (30.18) when $d \ll ct_1$.

frequency ΔF as

$$\Delta F = 2bT. \quad (30.21)$$

30.11.2 CTFM TOF Estimation

Echoes are generated when the transmitted wavefront encounters reflectors and are an attenuated, delayed version of the transmitted signal

$$E(t) = AS \left(t - \frac{2R}{c} \right), \quad (30.22)$$

where R is the range to the reflector, c is the speed of sound and A is the amplitude that may in the case of curved objects depend on the frequency of the sound at reflection.

The TOF is estimated by the two step process of demodulation and spectral analysis. Demodulation is achieved by multiplying the received signal by a copy of the transmitted signal and low pass filtering. This can best be understood in the simple case of one echo. The

signal $D(t)$ is obtained using (30.20) and (30.22)

$$\begin{aligned}
 D(t) &= E(t)S(t) \\
 &= \frac{A}{2} [\cos(2\pi f_e t - \phi) \\
 &\quad + \cos(2\pi f_u t - 2bt^2 - \phi)] \\
 \text{for } f_e &= \frac{4Rb}{c}, \\
 f_u &= \left(2f_H + \frac{4Rb}{c}\right), \\
 \phi &= f_H \frac{2R}{c} + \frac{4bR^2}{c^2}, \tag{30.23}
 \end{aligned}$$

where the following trigonometric identity has been used in (30.23)

$$\cos(x)\cos(y) = \frac{1}{2}[\cos(x-y) + \cos(x+y)]. \tag{30.24}$$

A low-pass filter removes frequency components above f_H and this results in the base-band signal

$$D_b(t) = \frac{A}{2} \left[\cos\left(2\pi \frac{4Rb}{c} t - \phi\right) \right], \tag{30.25}$$

which has a frequency proportional to the range R . The ranges of echoes can be extracted by examining the spectrum of D_b using, for example, a discrete Fourier transform (DFT) or the fast Fourier transform (FFT). From (30.25) for a frequency peak of f_r Hz the corresponding range R is given by

$$R = f_r \frac{c}{4b}. \tag{30.26}$$

Note that the above analysis relies on excluding the receiver waveform at the start of each sweep for a *blind time* (Fig. 30.21) of $R_m/2c$, where R_m is the maximum target range. During this blind time the receiver signal is dependent on the previous sweep rather than the

Fig. 30.21 18 Plot of frequency versus time for CTFM. The blind time applies if the shown echo corresponds to a maximum range target at R_m

current sweep as assumed in the analysis above. The sweep time T needs to be much larger than this blind time for the sonar to operate effectively. The blind time can be eliminated at the expense of introducing complexity in the demodulation process as described in [30.57], where an interlaced double demodulation scheme is described.

30.11.3 CTFM Range Discrimination and Resolution

We define range discrimination as the separation in range of two targets that can be simultaneously detected as distinct. The range resolution is defined as the smallest increment in range that can be measured by the sonar.

Suppose that, in order to extract ranges of targets, $D_b(t)$ from (30.25) is sampled at ΔT intervals and k samples are collected before a DFT (or FFT) is performed. The frequency samples of the DFT will be $\Delta f = 1/(k\Delta T)$ apart. From (30.26), this represents a range resolution ΔR of

$$\Delta R = \frac{c\Delta f}{4b} = \frac{c}{4bk\Delta T}. \tag{30.27}$$

We can relate this to the swept frequency ΔF from (30.21) as

$$\Delta R = \frac{c}{2\Delta F} \times \frac{T}{k\Delta T}, \tag{30.28}$$

where the second term is the ratio of the sweep time to the spectral sample time. In order to discriminate two peaks in the DFT, they must be at least two samples apart and hence

$$\text{range discrimination} = \frac{c}{\Delta F} \times \frac{T}{k\Delta T}. \tag{30.29}$$

Note that (30.28),(30.29) show that, subject to signal-to-noise constraints, CTFM can lengthen the *data integration time* $k\Delta T$ in order to improve the range discrimination and resolution of the sonar. Also it is possible, subject to signal noise, to use interpolation techniques (e.g., parabolic interpolation) on the DFT peaks to resolve to a smaller than Δf frequency and hence improve range resolution (but not range discrimination).

30.11.4 Comparison of CTFM and Pulse-Echo Sonar

- The range resolution of pulse-echo sonar and CTFM sonar is theoretically the same given the same signal-to-noise ratios and bandwidths [30.57].

The range discrimination in pulse-echo sonar is limited by the pulse length, where shorter pulse lengths require higher bandwidth. However in CTFM, range discrimination can be improved by increasing the data integration time, allowing more design flexibility.

- CTFM also allows for the energy of the transmitted signal to be spread evenly over time, resulting in lower peak acoustic power emission compared to pulse-echo systems with the same receiver signal-to-noise ratio. CTFM can provide a greater average power in a practical context and consequently a greater sensitivity to weak reflectors is possible.
- CTFM requires more-complex transmitter circuitry and the requirement for FFT processing on the receiver side.
- Separate transmitter and receiver transducers are necessary with CTFM, whilst pulse-echo systems can use a single transducer for both transmission and reception, resulting in restriction on the minimum range of pulse-echo sonar due to the blanking of the receiver during transmission. CTFM has no inherent restriction on minimum range.
- CTFM sonar can continuously derive range information from targets every $k\Delta T$ seconds at a delay of $R/c + k\Delta T$ compared to every $2R_m/c$ with a delay of $2R/c$ in pulse-echo sonar (ignoring processing delays in both), which may be important in real-time tracking applications.
- Other benefits of CTFM are that the number of range measurements per cycle is limited only by the range discrimination constraint of (30.28) and the signal-to-noise ratio.
- In terms of bearing estimation and classification of targets from a moving platform, short pulse-echo sonar systems like [30.27, 51] do not suffer from the CTFM data integration time required to estimate accurately the frequencies corresponding to ranges (and hence bearing). During the data integration time, the target can move with respect to the sensor and blur the measurements, making bearing estimation and classification less accurate. In short pulse-echo systems, the target is effectively sampled with a pulse of less than 100 μ s, resulting in a consistent snapshot of the target.

30.11.5 Applications of CTFM

Kay [30.58, 59] developed a mobility aid for blind people using a CTFM sonar system based on a sweep of $f_H = 100$ down to 50 kHz with a sweep period of $T = 102.4$ ms. After demodulation, ranges are heard as audible tones with frequencies up to 5 kHz corresponding to ranges of up to 1.75 m. The system

uses one transmitter and three receivers as shown in Fig. 30.22.

Users of the system can listen to the demodulated signal in stereo headphones corresponding to the left and right receivers, each mixed with the large central oval receiver. Higher frequencies correspond to more-distant ranges. To illustrate the sensitivity, a 1.5 mm-diameter wire is easily detectable at 1 m range – the echo produced is 35 dB above the noise floor in the system.

CTFM sonar has been used to recognize isolated plants [30.41, 60]. The advantage gained from CTFM is that extensive range and echo amplitude information is obtained from the whole plant given the spectrum of the demodulated received signal, and these echoes are obtained from an excitation across an octave of frequencies from 100 down to 50 kHz with a high signal-to-noise ratio that allows weak reflections from leaves to be sensed. This information is called the *acoustic density profile* and 19 different features are found to be useful in classifying the plants, such as the number of range cells above a threshold in amplitude, the sum of all range cells, the variation about the centroid, the distance from the first to the highest amplitude cell, and the range over which reflections are detected. With a population of 100 plants, an average of 90.6% correct pairwise classification was obtained using a statistical classifier.

Fig. 30.22 Aid for blind people – the small oval transducer is the transmitter and the other three components are receivers. The large oval receiver provides high resolution, enabling fixation by users' fine neck control (after Kay [30.58])

Scanning **CTFM** with a single transmitter and single receiver has been successfully applied to mapping of indoor environments that include smooth and rough surfaces [30.55] with bearing errors on the order of 0.5° for smooth surfaces and higher for edges. The classification uses amplitude information that is normalized with range using a fixed attenuation constant of sound. In practice this attenuation constant varies with temperature and humidity and needs to be calibrated before each experiment for consistent results. Greater robustness, speed, and accuracy has been demonstrated with **TOF** methods of classification that require at least two transmitter positions and two receivers as described in [30.11, 51]. **CTFM** could be applied to array systems to achieve higher sensitivity to weak targets than the existing pulse-echo systems.

CTFM has been employed in three binaural systems [30.12] where a rigorous theoretical and experimental comparison of these ultrasonic sensing systems based on different range and bearing estimators is made. *Stanley* [30.12] also contains detailed engineering design information of **CTFM** sonar systems. The conclusion is that **CTFM** can insonify large areas due to its higher average power transmissions and consequently good signal to noise performance. The use of autoregressive estimators for spectral lines in the demodulated signal were found to provide better resolution than the **DFT**. The interaural distance and power difference **CTFM** approaches provided state-of-the-art performance except that the pulse-echo approach in [30.11] using a high-energy short pulse was found to be a *factor of six to eight* times superior in bearing precision.

30.12 Multipulse Sonar

This section examines sonar systems that employ more than one pulse in the transmitter(s). The main motivations are interference rejection and on-the-fly classification. Multipulse sonar has also been used to generate a better signal-to-noise ratio by creating longer transmitted pulse sequence using Barker codes [30.61]. The autocorrelation of a Barker code gives a narrow peak with low autocorrelation away from the central lobe. The matched filter then gives rise to pulse compression that averages noise over a longer time period.

30.12.1 Interference Rejection

External acoustic noise, such as compressed air, is a source of sonar interference. Sonar systems attempt to reduce the effects of external interference by filtering the signal and the optimal filter is the matched filter where the impulse response is the time reversal of the pulse shape that is expected. Since a time-reversed convolution is a correlation, the matched filter then acts as a correlation with the expected pulse shape as discussed in Sect. 30.10. Approximations to matched filtering can be designed based on a bandpass filter with a frequency response that is similar to the spectrum of the expected receiver pulse. **CTFM** systems allow robust suppression of external interference by employing a matched filter across a broad range of frequencies contained in the continuous chirp transmission.

When more than one sonar system operates in the same environment, the transmitted signal from one sonar system can be received by another, causing crosstalk errors. This is particularly evident in classical

sonar rings constructed from Polaroid ranging modules. Error-eliminating rapid ultrasonic firing strategies have been developed [30.62] and are claimed to remove most of this interference and allow faster operation of these sonar rings.

More-sophisticate coding of transmitted pulse(s) has been employed [30.23, 63–66] to allow rejection of external interference and crosstalk. One difficulty with multiple transmitted pulses over a greater time period than a single pulse is that target clutter can produce many overlapping pulses at the receivers that are difficult to unravel and interpret, and the sonar range discrimination can be compromised.

30.12.2 On-the-Fly Target Classification

Target classification into planes, cylinders, and edges has been achieved by deploying a single transmitter and three receivers [30.25] using a single measurement cycle. At least two transmitters are required to differentiate planes from concave right-angled corners [30.11] where a two transmitter arrangement is used to classify targets into planes, corners, and edges in two successive measurement cycles. The method of classification can be understood with virtual images and mirrors, since specular sonar reflections occur. Looking into a plane mirror gives an image that is left-right reversed compared to looking into a right-angled mirror. An edge is analogous to observing a high-curvature specular surface, such as a polished chair leg, where the whole image is compressed to a point. Sonar classification exploits the difference in bearing angles to a target from

two transmitters to classify as follows: a positive difference δ indicates a plane, a negative δ value indicates a corner, and zero difference an edge, where the angle δ depends on the sensor geometry and target range. More sophistication can be added by using range measurements in addition to bearing, with maximum-likelihood estimation.

This arrangement [30.11] was refined to work with just one measurement cycle of around 35 ms to 5 m range: hence the term *on-the-fly* in [30.51]. This on-the-fly approach uses pulses fired at a precise time difference ΔT and 40 mm apart from two transmitters

with two further receivers completing a square. ΔT is usually around 200 μ s but can vary randomly from cycle to cycle to achieve interference rejection (both crosstalk and environmental) with identical sonar systems. Classification is performed simultaneously in one measurement cycle. The sensor achieves high accuracy in range and bearing with robust classification by exploiting the tight correlation between TOF jitter in the different transmitter to receiver paths due to the close temporal and spatial arrangement. The sensor has been deployed for large-scale mapping in [30.67].

30.13 Sonar Rings and Arrays

Since sonar only detects objects lying within its beam, a common means to scan the entire environment outside the robot is to use an array of sonars, or a *ring* [30.68].

30.13.1 Simple Ranging Module Rings

The most common is the Denning ring that contains 24 sonars equally spaced around the robot periphery. This 15° spacing allows some overlap in the sonar beams so at least one of the sonars will detect a strong reflecting object. The sonars in the ring are typically employed sequentially one at a time. Using a 50 ms probing pulse period to reduce false readings a complete environmental scan is accomplished every 1.2 s. This sample time is adequate for a translate-and-stop operation in research settings, but may be too slow for a continually moving robot. A robot moving at 1 m/s may not detect an object with sufficient warning to prevent a collision. Some researchers propose simultaneously employing sonars on opposite ends of the ring to speed up acquisition times, while others also reduce the probing pulse period and attempt to identify artifacts.

30.13.2 Advanced Rings

Yata et al. [30.53] developed a 32 cm-diameter sonar ring with 30 transmitters and 30 receivers placed alternately. Murata piezoelectric MA40S4R wide-angle transducers are used to enable overlapping reception of echoes produced by firing all the transmitters simultaneously. An axial symmetrical exponential horn structure is used to narrow the beam shape of the transmitters vertically to avoid reflections from the floor. Received signals are compared with a decaying threshold to produce a 1 bit digitized sampled signal without rectification. Bearing is estimated from the leading edge

of echoes and an error standard deviation of 0.4° is reported for ranges up to 1.5 m.

A sonar ring with seven digital signal processors (DSPs) [30.52, 69, 70] that uses 24 pairs of 7000 series Polaroid transducers consisting of a transceiver and receiver has been developed (Fig. 30.23). Each pair can derive range and accurate bearing information using template-matching digital signal processing (Sect. 30.10) on each of the two receiver channels, which are sampled at 250 kHz with 12 bit analog to digital converters. In total eight receiver channels are processed per DSP. All transceivers are fired simultaneously to enable full surrounding sensing of the environment approximately 11 times a second to a 6 m range with experimentally validated range and bearing accuracies to smooth targets of 0.6 mm and 0.2°, respectively. To suppress interference between neigh-

Fig. 30.23 DSP sonar ring hardware

boring pairs, two different transmitted pulse shapes are employed in an interleaved fashion around the perimeter of the ring. The pulse shapes are derived from two and three cycles of 65 kHz excitation. The

DSP sonar ring allows rapid and accurate wall following, map building, and obstacle avoidance due to the high repetition and accurate range and bearing sensing. The beam width of the transducer pairs allows full 360° coverage with respect to smooth specular targets to a range of 3 m. An example of the DSP sonar ring producing a feature for a simultaneous localization and mapping (SLAM) map is shown in Fig. 30.24.

30.13.3 Sonar Rings with FPGA Hardware Processing

One of the limitations of DSP based implementation of the signal processing arrangements such as [30.52, 69, 70] is that insufficient processing is available to perform matched filtering on the complete receiver echo signals in a multi-channel sonar ring. That is selected segments of the echo are processed where the signal exceeds a threshold in order to limit the computational load on the DSP processors. Once the full echo has arrived, matched filtering is then applied to these segments. More recent work [30.71, 72] describes a sonar ring that processes the complete echo signals from 48 receivers as the signal arrives with matched filtering. Complete processing of the entire receiver signal allows weak echoes to be detected that would be below the threshold of segmentation in [30.52, 69, 70]. This is achieved using a single field programmable gate array (FPGA) configured with a custom data path hardware design performing 4.9 Giga-arithmetic operations per

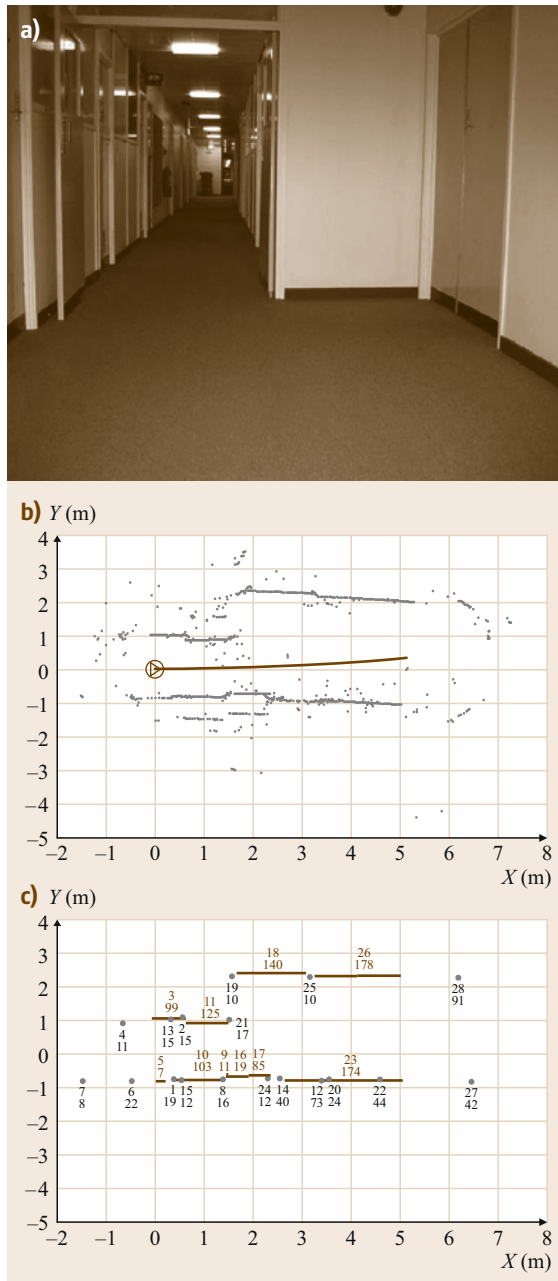

Fig.30.24a–c DSP sonar ring mapping an indoor environment (a), raw data (b) and SLAM feature map with feature number and number of associations shown as numbers (c). The sonar ring is moving at 10 cm/s with a 11.5 Hz sampling rate

Fig. 30.25 FPGA based sonar ring

second.  VIDEO 313 shows DSP sonar tracking an object. Range and bearing measurements are obtained at a rate of 30 Hz to 4 m range with full surrounding 360° angular coverage.

A photo of the FPGA sonar ring is shown in Fig. 30.25. Note that two layers of receivers are employed to reduce the radius of the 48 receiver ring. The other notable feature is the use of a single transmitter at the center of the ring. The transmitter is a hemispheric tweeter ESTD01 from Murata and a conical parabolic reflector to distribute the transmitter pulse uniformly in all directions horizontally [30.73]. Two cycles of a 48 kHz sine wave form the transmitter pulse. The transmitter can be modelled as point source and the pulse shape is approximately invariant with respect to received angle for each pair of receivers. This simplifies the matched filtering since the template for each receiver pair does not depend on the receiver angle. However there is some variation of pulse shape between different pairs in practice and as a function of range. The template match correlation processing hardware has been designed to allow dynamic switching of the template at predetermined ranges to account for the range variation of the pulse shape.

30.13.4 Double Refresh Rate Sonar Ring

Sonar rings have been limited in their firing rate by waiting for maximum range echoes to return before a consecutive firing of the transmitter. For example, the FPGA sonar ring presented in [30.71] is limited to 30 Hz refresh rate by this constraint. A double refresh rate FPGA sonar ring is presented in [30.74] that operates at 60 Hz for a 5.7 m range. To achieve a double refresh rate, the next sonar transmission is scheduled by selecting a transmit time from a random set so as to minimize interference with predicted echo arrival

times. Two matched filters are applied to the receiver signal based on the two possible transmit times. Echoes are associated with a transmit epoch with the following criteria:

- The arrival time must be consistent with previous echoes since this is bounded by the sensor to obstacle relative speed
- The pulse energies should be within 50% of a previous echo from the same obstacle, and finally
- The template match correlation must be acceptable for the assumed range.

30.13.5 Sparse 3-D Arrays

The work by *Steckel et al.* [30.75] presents a sonar system that borrows beamforming theory from the design of antenna arrays. The sonar array is based on a sparse random array of 32 condensor omnidirectional ultrasonic microphones and a single Polaroid 7000 acting as a transmitter. The microphone signals are sampled at a maximum rate of 500 kHz and processed by an FPGA to produce a measurement repetition rate of 12 Hz. The transmitter waveform is a carefully controlled hyperbolic chirp of 100 down to 20 kHz in 3 ms. Matched filtering and beamforming processing are applied to the received signals to generate an energy scape – the distribution of energy from reflectors from discrete directions of around 1° resolution. Experiments show the system can discriminate 20 mm diameter poles at 800 mm with 5° separation. The minimum angular separation is related to the width of the mainlobe of the spatial array filters. Azimuth and elevation standard deviations of errors are reported as 1.1 and 0.6° respectively for a 80 mm sphere at 1.5 m. The advantage of the system is its ability to discriminate overlapping echoes in cluttered environments.

30.14 Motion Effects

When a sensor moves with respect to its targets, sonar measurements are effected. For example, a sonar sensor moving at a speed of 1% of the speed of sound (around 3.4 m/s) will experience errors of the order of 0.6° for some bearing measurements. The effects of linear velocity on the TOF and reception angle are dependent on the target type and hence for motion compensation to be meaningful a target classification sensor is needed. We consider the classical plane, edge, and corner target types in this section. Rotational motion effects are discussed in [30.27] where it is shown that very high speeds of rotation are necessary to give rise to

a small bearing error (e.g., 0.1° error for approximately 1700 deg/s). Narrowing of the effective beam width is another effect of high rotation speeds of a sonar sensor.

The sensor is assumed to transmit from a point labeled T and receiver measurements are referenced to this position on the sensor. However, due to the motion of the sensor, the ground referenced position R at the time of reception of the echo moves from T over the course of the TOF. For a linear velocity, the distance between T and R is $\text{TOF} \times v$, where v is the magnitude of the sensor velocity vector relative to the ground, with components v_x and v_y parallel to their respective

Fig. 30.26 Observation of arriving wave from a moving observer ◀

coordinate axes. The expressions derived for linear motion apply to any sonar sensor, since only the physics of sound propagation and reflection are used. All targets are assumed to be stationary.

This section is based on [30.27], where further experimental work not included here can be found.

30.14.1 Moving Observation of a Plane

A plane target reflects the transmission from position T to R as shown in Fig. 30.26a. The TOF is broken up into two parts: t_1 is the time of propagation to the plane and t_2 from the plane to the receiver R. Here we derive the effect of linear motion on the $\text{TOF} = t_1 + t_2$ and the angle of reception θ all taken from the view of a *stationary* observer. A moving observer is discussed below.

From the right-angle triangle on the left of Fig. 30.27 a, we have

$$\sin \theta = \frac{v_x}{c} \text{ and } \cos \theta = \sqrt{1 - \left(\frac{v_x}{c}\right)^2} \quad (30.30)$$

and also

$$\cos \theta = \frac{d_1}{t_1 c} \implies t_1 = \frac{d_1}{c \cos \theta} . \quad (30.31)$$

From the right-angled triangle on the right of Fig. 30.27 a, we have

$$\begin{aligned} \cos \theta &= \frac{(t_1 + t_2)v_y + d_1}{t_2 c} \\ \implies t_2 &= \frac{(t_1 + t_2)v_y + d_1}{c \cos \theta} . \end{aligned} \quad (30.32)$$

The TOF is obtained by adding (30.31) and (30.32) and then substituting (30.31) giving

$$\text{TOF} = \left(\frac{2d_1}{c}\right) \frac{1}{\sqrt{1 - \frac{v_x^2}{c^2} - \frac{v_y}{c}}} . \quad (30.33)$$

The first factor in (30.33) represents the stationary TOF . The second factor approaches unity as the velocity approaches zero.

30.14.2 Moving Observation of a Corner

Figure 30.27 b shows the situation for a corner with the virtual image of T is shown as T'. From the right-angled triangle T'XR

$$c^2 \text{TOF}^2 = (2d_1 + v_y \text{TOF})^2 + v_x^2 \text{TOF}^2 , \quad (30.34)$$

Fig. 30.27a–c Observing a target from a moving sensor. T is the position of the transmitter and R is where the echo is received at the end of the TOF . The target is a plane in (a), a corner in (b), and an edge in (c)

which gives

$$\text{TOF} = \frac{2d_1}{c} \left(\frac{\sqrt{1 - \left(\frac{v_x}{c}\right)^2} + \frac{v_y}{c}}{1 - \left(\frac{v}{c}\right)^2} \right), \quad (30.35)$$

where $v^2 = v_x^2 + v_y^2$. The left-hand term of (30.35) is the stationary **TOF** and the right-hand term approaches unity for small velocities. The angle ϕ in Fig. 30.27 b is the angle deviation due to motion as reference by a stationary observer. From the triangles T'XR and CXR

$$\begin{aligned} \tan \theta &= \frac{v_x \text{TOF}}{2d_1 + v_y \text{TOF}} \quad \text{and} \\ \tan(\theta + \phi) &= \frac{v_x \text{TOF}}{d_1 + v_y \text{TOF}}. \end{aligned} \quad (30.36)$$

From (30.36), we have

$$\tan(\theta + \phi) = \left(2 - \frac{v_y \text{TOF}}{d_1 + v_y \text{TOF}} \right) \tan \theta \quad (30.37)$$

and solving for $\tan \phi$ yields

$$\begin{aligned} \tan \phi &= \tan \theta \left(\frac{1 - \sin^2 \theta}{\frac{v_y \text{TOF}}{d_1} + 1 + \sin^2 \theta} \right) \\ &= \left(\frac{v_x}{\frac{2d_1}{\text{TOF}} + v_y} \right) \left(\frac{1 - \sin^2 \theta}{\frac{v_y \text{TOF}}{d_1} + 1 + \sin^2 \theta} \right). \end{aligned} \quad (30.38)$$

For $v_x, v_y \ll c$, $\sin \theta \ll 1$ and $2d_1/\text{TOF} \approx c$ we can approximate (30.38) as

$$\phi \approx \frac{v_x}{c}. \quad (30.39)$$

30.14.3 Moving Observation of a Edge

Since an edge reradiates the incoming ultrasound from an effective point source, the reception angle with respect to a stationary observer is unaffected by motion as shown in Fig. 30.27 c. The **TOF** is affected due to the motion moving the receiving position. From the right-angled triangle XER, $d_2^2 = (d_1 + v_y)^2 + v_x^2 \text{TOF}^2$ and $d_1 + d_2 = c\text{TOF}$ leads to

$$\text{TOF} = \frac{2d_1}{c} \left(\frac{1 + \frac{v_y}{c}}{1 - \frac{v^2}{c^2}} \right) \approx \frac{2d_1}{c} \left(1 + \frac{v_y}{c} \right), \quad (30.40)$$

where the approximate holds in (30.40) for $v \ll c$.

30.14.4 The Effect of a Moving Observation on the Angle of Reception

The expressions for the reception angle in the previous sections are based on an observer that is stationary with respect to the propagating medium air. In practice the observer is the sensor, and is moving with a velocity v . Suppose that the sonar wave arrives at an angle α relative to the air, as shown in Fig. 30.26.

The velocity components of the wavefront relative to the observer, w_x and w_y , are as follows

$$w_x = c \sin \alpha - v_x \quad \text{and} \quad w_y = c \cos \alpha - v_y. \quad (30.41)$$

From (30.41) the observed angle of arrival, β is

$$\tan \beta = \frac{c \sin \alpha - v_x}{c \cos \alpha - v_y} = \frac{\sin \alpha - \frac{v_x}{c}}{\cos \alpha - \frac{v_y}{c}}. \quad (30.42)$$

30.14.5 Plane, Corner, and Edge Moving Observation Arrival Angles

In this section the arrival angles (in radians) for each target type are summarized and approximated for speeds expected of a mobile robot. The speed is assumed to be less than a few percent of the speed of sound (typically 340 m/s at room temperature). These effects have been observed experimentally at speeds of up to 1 m/s [30.27].

Equations (30.41) and (30.30) cancel exactly, and for a plane the arrival angle relative to the sensor is exactly zero

$$\beta_{\text{plane}} = 0. \quad (30.43)$$

This can be explained by noting that the forward wave velocity component is always the same as the sensor's as reflection preserves this component.

For a corner the angle ϕ results in a wavefront that appears to be displaced in the same direction as the sensor motion from the real corner direction, as can be seen in Fig. 30.27 b. The effect of the moving observer doubles this effect as seen by (30.41) and (30.39)

$$\beta_{\text{corner}} \approx -\frac{2v_x}{c}. \quad (30.44)$$

For an edge the result is due to the observer only

$$\beta_{\text{edge}} \approx \tan^{-1} \left(\frac{0 - \frac{v_x}{c}}{\cos \alpha - \frac{v_y}{c}} \right) \approx -\frac{v_x}{c}. \quad (30.45)$$

30.15 Biomimetic Sonars

The success of biosonars, bats and dolphins [30.76], has led researchers to implement sonars based on biosonar morphology, strategy, nonlinear processing and cleverness [30.77]. The capabilities exhibited by biosonars have caused researchers to examine biomimicking (*biomimetic*) systems.

Biosonar morphology typically has a single transmitter and a pair of receivers. Bats transmit sound pulses through the mouth or nose, while dolphins transmit through a melon. The two receivers correspond to ears that permit binaural processing. Mimicking binaural hearing has led to small arrays that localize objects [30.8] and scanning strategies [30.78].  VIDEO 311,  VIDEO 316,  VIDEO 317 show biomimetic sonars in action. Movable pinnae observed in bats have motivated research

in receivers that rotate [30.79, 80] and deform [30.81].  VIDEO 312 shows pinna deformation. Figure 30.28 shows one such example.

Rotating the receivers so their axes fall onto the reflecting object not only increases the detected echo amplitude, but also its bandwidth, both effects improving the ability to classify an object.

Biosonar strategy provides clues for successful object localization. It is well known that the object location within the transducer beam affects the echo waveform and complicates the inverse problem of object classification [30.10, 82]. Dolphin movies show that they maneuver to position an object at a repeatable location and range, guided by binaural echo processing. This has motivated a dolphin-mimicking movable sonar positioned at the end of a robot arm for object classification [30.10, 82], as shown in Fig. 30.29.

Fig. 30.28 Biomimetic configuration sonar with center transmitter flanked by receivers that rotate

Fig. 30.29 Biomimetic sonar mounted on the end of a robot arm

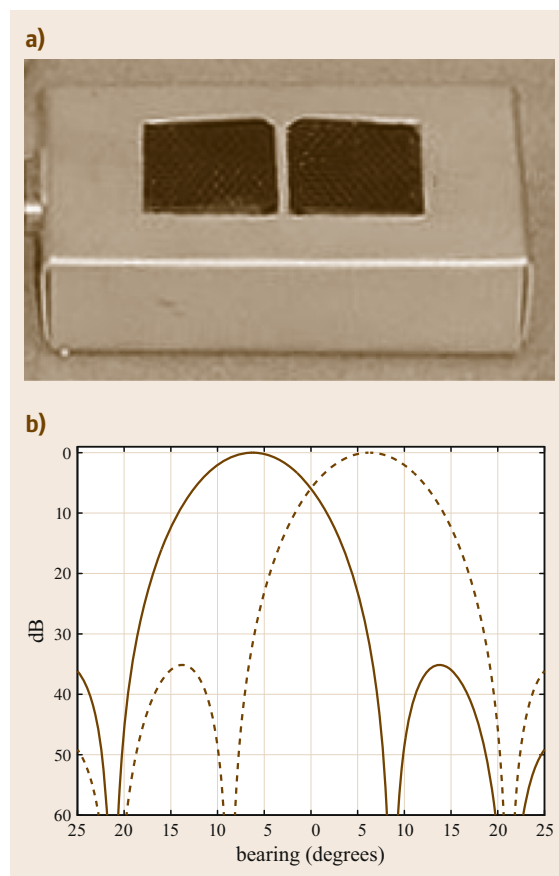

Fig. 30.30a,b Binaural vergence sonar (a) and beam patterns (b) along the sonar axis with vergence angle $\alpha = 8^\circ$: solid-left transducer, dashed-right transducer

This system was able to differentiate reliably the head and tail side of a coin, but only after introducing a scan in elevation to accommodate for the lack of such positioning afforded by binaural hearing. The idea for a scan over elevation was motivated by the nodding motion that dolphins exhibit when searching for prey lying under the sand.

Another useful strategy, suggested by probing pulses emitted by bats, is processing echo sequences. As an extension to the conventional stop-and-scan operation of most sonars, sonar data were acquired while the sonar was moving along piecewise linear paths to reveal hyperbolic trends, similar to acoustic flow [30.83]. Matching data to hyperbolic trends permits the estimation of the passing range, which is useful for collision avoidance and passing through narrow openings [30.83].

Most sonar systems use classical estimation procedures involving correlation detection and spectrum analysis. The cochlear model has led to multiple band-pass filters to process wide-band pulses for environmental landmark classification [30.43]. The action potential spikes observed in the biological nervous system also suggest neuromorphic processing based on coincidence detection. The sparse information provided by conventional TOF measurements motivated sonar detectors that provided complete echo waveform information from multiple detections that result in spike-like data [30.24, 84]. Applying temporal and spacial coincidence to spike data has led to reverberation artifact recognition [30.36] and passing-range estimation [30.85].  VIDEO 302 shows a simulation of side-looking sonar passing two targets.  VIDEO 314 shows camera view of mobile robot traveling down corridor.  VIDEO 303 shows sonar spike map of corridor.

One shortcoming of sonar is its relatively wide beam that limits the accuracy of the reflector bearing estimate. Biosonars have two ears that assist in echolocation, with a strategy that is surprising for engineers. Figure 30.30 shows a biomimetic binaural sonar described in [30.86] that employs two Polaroid 6500

ranging modules connected to series-7000 ultrasound transducers (dia $d = 2.5$ cm), designated as *right* and *left*. Both transducers transmit emissions simultaneously, but each makes a TOF reading. The transducers are separated by D cm, with D minimized so that the incident echo wavefront is as similar as possible across both transducers. If both transducers are oriented parallel to the sonar axis, the TOF difference for an echo from an object at bearing θ is

$$\Delta\text{TOF} = \frac{D}{c} \sin \theta; , \quad (30.46)$$

which is small for small D .

While most sensor engineers would maximize signal strength by having both transducers point at the object, biological sonars trade off signal strength for improved localization by directing the ears away from the object with vergence angle α . This vergence angle spreads the sensitivity patterns away from the sonar axis, as shown in Fig. 30.30. As was shown in Fig. 30.12, this enhances ΔTOF by increasing the echo amplitude difference.  VIDEO 301 shows vergence sonar in operation.

Such a vergence sonar has several applications for mobile robots. By noting when both TOFs are nearly coincident, the binaural vergence sonar can detect when a reflecting object is within $\pm 0.1^\circ$ of the sonar orientation. This sonar is useful for mobile robot navigation because, in addition to a range measurement, it indicates whether an obstacle is to the left or right of the intended path.  VIDEO 295 shows mobile robot equipped with multiple vergence sonars. Also, the occlusion problem associated with sonar sensing is solved by placing vergence sonars on the outside limits of a robot to determine if an opening lies to the outside of the robot dimensions, thus allowing the robot to pass through narrow openings.

Such biomimetic techniques provide insights into the information content present in echoes and the type of sensing tasks for which sonar is best suited.

30.16 Conclusions

Sonar is a useful, inexpensive, low-power, light-weight and simple ranging sensor for robotics applications that can provide accurate object localisation. For sonar to be effectively employed, understanding its physical principles and implementation is important and these topics are covered in the early sections of this chapter. Various approaches to sonar sensing are highlighted from simple single-transducer ranging to more sophis-

ticated multi-transducer and multi-pulse configurations with associated signal processing requirements. Sophisticated sonars are capable of measuring target range and angle accurately as well as classifying targets, rejecting interference, and compensating for motion. Sonar rings provide surrounding environmental coverage, and CTFM systems improve the sensitivity for detecting small reflectors. Research is ongoing in areas such as

signal and data processing, sonar map building, sonar configurations, transducer technology and biomimetic

sonar that draw inspiration from biological sonar systems, such as used by bats and dolphins.

31. Range Sensing

Kurt Konolige, Andreas Nüchter

Range sensors are devices that capture the three-dimensional (3-D) structure of the world from the viewpoint of the sensor, usually measuring the depth to the nearest surfaces. These measurements could be at a single point, across a scanning plane, or a full image with depth measurements at every point. The benefits of this range data is that a robot can be relatively certain where the real world is, relative to the sensor, thus allowing the robot to more reliably find navigable routes, avoid obstacles, grasp objects, act on industrial parts, etc.

This chapter introduces the main representations for range data (point sets, triangulated surfaces, voxels), the main methods for extracting usable features from the range data (planes, lines, triangulated surfaces), the main sensors for acquiring it (Sect. 31.1 – stereo and laser triangulation and ranging systems), how multiple observations of the scene, for example, as if from a moving robot, can be registered (Sect. 31.3) and several indoor and outdoor robot applications where range data greatly simplifies the task (Sect. 31.4).

31.1 Range Sensing Basics

Here we present the basic representations used for range image data and discuss some issues relating to representations and robotics applications. While there are ranging devices that use sound or other waves to determine distance, this chapter concentrates on sensors that use light.

31.1.1 Range Images and Point Sets

Range data is a two-and-a-half-dimensional (2.5-D) or 3-D representation of the scene around the robot.

The 3-D aspect arises because we are measuring the (X, Y, Z) coordinates of one or more points in the scene. Often only a single range image is used at each time instance. This means that we only observe the front sides of objects – the portion of the scene visible from the robot. In other words, we do not have a full 3-D observation of all sides of a scene. This is the origin of the term 2.5-D. Figure 31.1 shows a sample range image and a registered reflectance image, where each pixel records the level of reflected infrared light.

Fig. 31.1a,b 3-D laser scan with a field of view of $360^\circ \times 100^\circ$ acquired in an urban environment (Bremen downtown). (a) Registered infrared reflectance image. (b) Range image where closer is darker

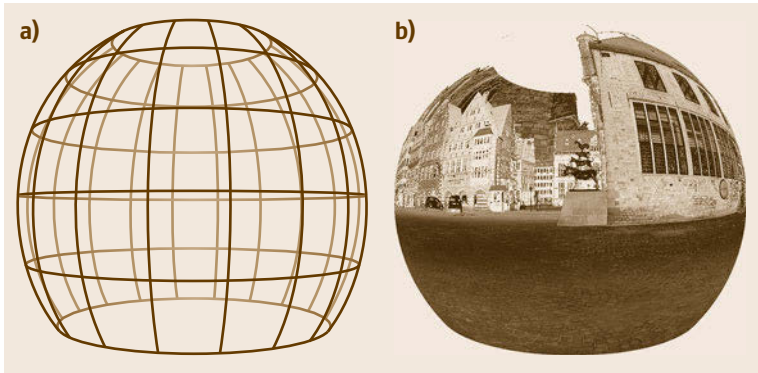

Fig. 31.2 (a) Mesh showing the rasterization of a 3-D range scanner using rotating mirrors and axis. (b) Sphere with superimposed reflectance values

There are two standard formats for representing range data. The first is an image $d(i,j)$, which records the distance d to the corresponding scene point (x,y,z) for each image pixel (i,j) . There are several common mappings from $(i,j,d(i,j))$ to (X,Y,Z) , usually arising from the geometry of the range sensor or from the application needs. The most common image mappings are illustrated in Fig. 31.3. Range scanners with rotating mirrors sample in spherical coordinates, that is,

Fig. 31.3 (a) Equirectangular projection of a spherical range scan. Latitude and longitude mesh is shown. (b) Rectilinear projection with three images compined to unwrap a scanning sphere ►

Fig. 31.4 3-D range scan represented with three rectilinear projections (Fig. 31.1)

(θ, φ, d) . Figure 31.2 shows a sphere as longitude and latitude mesh and superimposed with the reflectance values of Fig. 31.1. The most natural range image representation is to put (θ, φ) on the (i, j) -axis of the range image, that is,

$$\begin{aligned} i &= \theta, \\ j &= \varphi, \end{aligned}$$

where the longitude θ and the latitude φ are the spherical coordinates. This is a projection of the samples sphere to a two-dimensional (2-D) image, which includes a distortion. The conversion between $(i, j, d) = (\theta, \varphi, d)$ and (x, y, z) proceeds as

$$\begin{aligned} d &= \sqrt{x^2 + y^2 + z^2}, \\ \theta &= \arccos\left(\frac{z}{r}\right), \\ \varphi &= \arctan2(y, x). \end{aligned}$$

Conversely, the Cartesian coordinates may be retrieved from the spherical coordinates by

$$\begin{aligned} x &= d \sin \theta \cos \varphi, \\ y &= d \sin \theta \sin \varphi, \\ z &= d \cos \theta. \end{aligned}$$

The further common projection is the perspective one, usually called rectilinear projection. It is also called *gnomonic* or *tangent-plane* projection. This include range images produced by kinetic-like devices. Here the

range values are assumed to be projected in a pinhole camera like fashion. The primary advantage of the rectilinear projection is that it maps straight lines in the 3-D space and in the 2-D image. Its disadvantage is the smaller field of view (FOV). The projection is stretched toward the corners and the distortion grow with larger fields of view. Furthermore, FOVs are often not realizable by the hardware. The projection proceeds as

$$\begin{aligned} i &= \frac{\cos \varphi_1 \sin(\theta - \theta_0)}{\sin \varphi_1 \sin \varphi + \cos \varphi_1 \cos \varphi \cos(\theta - \theta_0)}, \\ j &= \frac{\cos \varphi_1 \sin \varphi - \sin \varphi_1 \cos \varphi \cos(\theta - \theta_0)}{\sin \varphi_1 \sin \varphi + \cos \varphi_1 \cos \varphi \cos(\theta - \theta_0)}, \end{aligned}$$

where θ_0 and φ_1 are the central longitude and central latitude, respectively. Figure 31.4 shows a 360° scan composed of three rectilinear range images.

Further common projections are the isogonic Mercator projection, the cylindrical projection, Pannini projection, and the stereographic [31.1]. All these projections are used to unwrap the scanning sphere to a 2-D array representation. In some applications, orthographic projections are processed from 3-D point cloud data. Some range sensors only record distances in a slice, so the scene (x, z) is represented by the linear image $d(i)$ for each pixel i .

The second format is as a list $\{(x_i, y_i, z_i)\}$ of 3-D data points, but this format can be used with all of the mappings listed above. Given the conversions from image data $d(i, j)$ to (x, y, z) the range data is only supplied as a list, which is usually called the point cloud.

31.2 Sensor Technologies

There are two main technologies for range sensing: triangulation and time-of-flight. There are many variations of each of these, with different strengths and weaknesses. Here we briefly describe the basic con-

cepts, and summarize the characteristics of the main types of sensors. More detailed descriptions of stereo and structured light sensors are given in subsequent sections.

31.2.1 Triangulation

Triangulation sensors measure depth by determining the angle formed by the rays from a world point to two sensors. The sensors are separated by a baseline of length b , which forms the third segment of a triangle between the two sensors and the point. For simplicity, let one of the rays form a right angle with the baseline. Then the angle θ of the other sensor ray is related to the depth Z perpendicular to the baseline by

$$\tan \theta = \frac{Z}{b}. \quad (31.1)$$

An image sensor measures the angle θ by an offset on an image plane from the primary ray; this offset x is called the *disparity*. If we assume that the image plane is parallel to the baseline, then $\tan \theta = f/x$, and we get the basic equation of triangulation depth sensors

$$Z = \frac{fb}{x}. \quad (31.2)$$

Depth Precision

An important concept is the *depth resolution* of a sensor: how precisely can the sensor measure the depth? Differentiating with respect to x and substituting for x gives

$$\frac{dZ}{dx} = \frac{-Z^2}{fb}. \quad (31.3)$$

Triangulation precision falls off with the square of the distance to an object: if it is 1 mm at 1 m, then it is 4 mm at 2 m. Increasing the baseline or reducing the field of views **FOV** is inversely related to precision, that is, if the baseline is doubled or **FOV** is halved, the precision is halved (e.g., from 1 mm at 0.1 m baseline to 0.5 mm at 0.2 m baseline). This makes triangulation sensors more difficult to use at a distance; changing the **FOV** or baseline can help compensate, but brings in other tradeoffs (Sect. 31.2.4).

Types of Triangulation Sensors

The two main types are stereo cameras, which have two cameras separated by a baseline, and structured light sensors, which substitute a projector for one of the cameras.

Stereo cameras take images of a scene from two slightly different viewpoints, and match texture in the images to determine corresponding points and disparities. Some issues with stereo cameras are that there is often too little texture, especially indoors, to make reliable matches; and the matching uses small patches, which blurs out the spatial resolution. Many ingenious methods have been developed to deal with these issues,

including painting a texture with a projector (not to be confused with structured light), using different kinds of support neighborhoods and regularization methods.

Structured light sensors project a known pattern from one end of a baseline, and view the pattern with a camera from the other. By decoding the pattern in the image, the placement of the pattern in the projector is determined, and hence the disparity. The simplest type of projectors output a point or a line, usually with a laser; the decoding problem is easy, but the amount of information is restricted to the point or line, and must be scanned to produce a full 3-D image.

A full-image structured light system projects a pattern covering the whole image, that can be decoded to get information at each pixel or small group of pixels. The PrimeSense technology, used in the Kinect, projects a known pattern of dots and decodes a small neighborhood to find the projected coordinates; thus this sensor also blurs out the spatial resolution. Other sensors project a time series of images with a vertical structure, so that each pixel on a horizontal line accumulates a unique code, which is then decoded against the projected images. Popular binary codes are Gray codes, which require N images if the image width is 2^N ; and sinusoidal phase-shifted patterns, which typically use three images and are decoded by determining the phase at each point. These time-series structured light systems can produce very good spatial and depth resolution.

In general, structured light systems are not used outdoors because of interference from natural light, and for distant objects indoors. They can also have difficulty with high-contrast and specular objects, and the phase-based systems can suffer from 2π phase ambiguities. Relative motion between the sensor and the scene can also distort readings for time series and scanning sensors, although very fast projectors and cameras can alleviate this problem for the former.

31.2.2 Time of Flight

The principle behind time-of-flight (**TOF**) sensors is like that of radar: measure the time it takes for light to be projected out to an object and return. Because light travels about 0.3 m per nanosecond, very precise timers are required for direct **TOF** measurement; an alternative is indirect methods, typically phase difference with a modulated reference beam.

Because they measure time of flight, these sensors can theoretically have constant precision in depth measurement, no matter how far an object – unlike triangulation sensors, which fall off as the square of distance. But **TOF** sensors cannot duplicate the very fine precision of triangulation sensors for close objects,

and hence are not used in close-range metrology applications, such as small object reconstruction or parts quality measurements.

Direct Time of Flight

In direct **TOF** sensors, the travel time is measured by a high-speed chronometer. Laser-based direct **TOF** range sensors are also called **LIDAR** (light detection and ranging) or **LADAR** (laser radar) sensors. The travel time multiplied by the speed of light (in the given medium – space, air, or water and adjusted for the density and temperature of the medium) gives the distance

$$2d = ct, \quad (31.4)$$

where d is the distance to the object, c is the speed of light, and t is the measured travel time. Error in measuring the time t gives rise to a proportional distance error. In practice, one tries to measure the peak of the output pulse, which has a finite extent; weak reflections from distant objects make it harder to measure this peak and hence the error tends to increase with distance. Averaging multiple readings can reduce the random error in these readings.

The simplest **TOF** sensors transmit only a single beam, thus range measurements are only obtained from a single surface point. Robotics applications usually need more information, so the range data is usually supplied as a vector of range to surfaces lying in a plane (Fig. 31.5) or as an image (Fig. 31.1). To obtain these denser representations, the laser beam is swept across the scene. Normally, the beam is swept by a set of mirrors rather than moving the laser and detector themselves (mirrors are lighter and less prone to motion damage). The most common technologies for this are using a stepper motor (for program-based range sensing) or rotating or oscillating mirrors for automatic scanning.

Scanning or averaging requires multiple **TOF** pulses at perhaps high repetition rates, which can give rise to

Fig. 31.5 Plot of ideal one-dimensional (1-D) range image of sample distance versus angle of measurement

ambiguity about which pulse is actually being received. If δt is the time between pulses, then the *ambiguity interval* for the device is $1/2c\delta t$, for example, for a pulse repetition rate of 100 kHz, the ambiguity interval is 1500 m. If an object is further than this, it will be seen as within the interval, with distance $\text{zmod} 1/2c\delta t$. An *unwinding algorithm* can recover the true depth, if range values for the scanning system change slowly, and start within the ambiguity interval.

Typical ground-based time of flight sensors suitable for robotics applications have a range of 10–100 m, and an accuracy of 5–10 mm. The amount of the scene scanned will depend on the sweep rate of the mirrors and the pulse rate, but 1–25k points per second are typical. Manufacturers of these sensors include Acuity, Hokuyo, Sick, Mensi, DeltaSphere, and Cyrax.

Multiple-beam scanning **LIDARs** can increase the amount of information available. Velodyne [31.2] makes three devices, with 16, 32, and 64 beams arranged vertically, that acquire point data at rates of up to 15 scans/s (1.3 MPixel/s), with a full 360° horizontal scan and a 27° vertical **FOV** from the laser array. The laser pulses are 5 ns long, and depth precision is approximately 2 cm. These devices are typically used in autonomous driving, for environment reconstruction and obstacle avoidance.

Flash LIDAR

In contrast to scanning devices, a *flash LIDAR* has a **2-D** detector array (also called a *focal plane array* similar to a camera imager, but where each pixel incorporates timing circuitry to measure **TOF** of a laser pulse). Instead of a single or multiple laser beams, a light source pulse (**LED** (light-emitting diode) or laser) is shaped to cover a large area. All pixels have their timers started when the pulse is initiated, and measure the time it takes to receive the backscattered light. Typically, some tens of samples are captured and averaged, to reduce noise in the measurements – the amount of energy received is quite small, since the laser is not focused into a beam. As might be expected, the detector array pixels are quite large because of the timing electronics; a typical device from ASC [31.3] has 128×128 pixels, and can capture data at rates up to 60 Hz (≈ 1 MPixel/s, similar to the Velodyne devices). These devices are expensive, and hence not used in consumer applications. Alternatively, indirect ways of measuring **TOF** have simpler per-pixel electronics – see the next subsection. Table 31.1 lists the characteristics of one of ASC's devices.

Table 31.1 Characteristics of TigerEye device

Manuf./Model	Resolution	Max range	Repeatability
ASC Inc. TigerEye	128×128	60–1100 m	0.04 m @ 60 m

Indirect Time of Flight Sensors

Indirect **TOF** sensors measure the distance by inferring transit times from particular properties of a propagating beam. The two main methods are based on *modulation and phase differences* and *gated intensity*.

Modulation-Based TOF

Modulation-based range sensors are commonly of two types, where a continuous laser signal is either amplitude or frequency modulated. By observing the phase shift between the outgoing and return signals, the signal transit time is estimated and from this the target distance.

Amplitude modulation works by varying the intensity of a light signal $s(t) = \sin(2\pi ft)$ with frequency f . The signal reflected from an object has a phase shift φ , and the returned signal is

$$r(t) = R \sin(2\pi ft - \varphi) = R \sin \left[2\pi f \left(t - \frac{2d}{c} \right) \right],$$

$$d = \frac{c\varphi}{4\pi f},$$
(31.5)

with c is the speed of light, d the distance to the object, and R the reflected amplitude. Measuring the phase shift yields the distance; note because the phase shift wraps around at 2π , the ambiguity interval is $c/2f$. For a modulation of 10 MHz, the interval is 15 m.

To measure the phase difference, the returned signal is mixed with the original reference signal and a 90° shifted version, then low-pass filtered. Figure 31.6 compares the two mixed signals that give both the phase difference and the intensity.

There are commercial devices using single-beam and planar array versions of amplitude modulation. The planar arrays take advantage of CMOS integration to implement the full signal comparison at each pixel, in a compact sensor [31.4, 5]. Because the signal-to-noise

Fig. 31.6 Comparing the two mixed signals gives both the phase difference and the intensity

ratio (**SNR**) depends on the amplitude of the returned signal, these devices typically have a depth resolution that falls off as d^2 , comparable to triangulation devices. Typical repeatability is about 3 cm at 0.5 m, significantly less than triangulation devices; the arrays are up to 200×200 pixels. The attraction of the planar array is that it is a single-chip ranging device, simple and potentially cheap to produce. They also have good ambient light rejection, and potentially can be used outdoors.

Frequency modulation, also called frequency modulation continuous wave (**FMCW**), modulates a laser frequency with a sawtooth ramp of period t_m , where the maximum frequency spread is Δf . The outgoing and incoming signals are mixed to give a signal difference f_i , which is measured by frequency counting. The distance is calculated as $d = f_i c t_m / 2 \Delta f$. Since the frequency difference can be measured very accurately, this technique can yield excellent depth precision, on the order of 5 mm at 2 m [31.6]. The electronics required for mixing and frequency counting, as well as the difficulty of linear laser frequency modulation, have restricted this technique to high-end single-beam devices [31.7].

Range-Gated Intensity

Another indirect method for measuring **TOF** of a pulse is to measure the amount of the pulse that gets returned within a precise time period. If a pulse of width w is emitted, a detector will start to receive the pulse reflected from an object of distance d at $t_0 = 2d/c$, and finish receiving it at $t_w = (w + 2d)/c$. If the detector is *open* for a precise amount of time t , then the amount of the reflected signal it receives, relative to the full pulse reflection, is a linear measure of the distance d . Thus, by comparing two returns, one with a large open time to measure the full pulse, and one with a smaller open time, d can be determined. A planar array CMOS device can be fabricated to measure the two pulse returns sequentially, as long as each pixel can be triggered to be photosensitive for a precise amount of time. Commercial devices using this principle have precision on the order of a few cm at 1 m, with arrays up to 128×96 [31.8, 9].

31.2.3 Comparison of Methods

A useful overall summary of different types of range-sensing technology is in reference [31.6]. The two main parameters are spatial precision and depth precisions. In Fig. 31.7, available sensors are classified along these two dimensions. The direct **TOF** laser scanners (**LMS**, **UT** devices) cluster around 0.5–1 cm in both spatial and range precision. The Photon80 device uses **FMCW**

modulation with outstanding spatial and range precision; it is also a scanning device.

Triangulation devices (stereo, Kinect, and structured light in general) have less favorable characteristics. However, the target is at 2 m, and with triangulation precision falling with d^2 , the comparison is biased. All these devices would be better than the TOF devices at 0.5 m in terms of range error. The stereo sensors can also exhibit much better spatial density in different configurations, that is, higher resolution sensors, larger baseline, smaller correlation window. In general, we would expect the triangulation sensors to outperform TOF sensors at shorter distances.

Finally, a single-chip flash LIDAR device, the IFM O3D200, uses amplitude modulation, and gives characteristically poor results relative to the other sensors.

31.2.4 Stereo Vision

This section discusses stereo analysis in more detail. Stereo analysis uses two or more input images to estimate the distance to points in a scene. The basic concept is *triangulation*: a scene point and the two camera points form a triangle, and knowing the baseline between the two cameras, and the angle formed by the camera rays, the distance to the object can be determined.

In practice, there are many difficulties in making a stereo imaging system that is useful for robotics applications. Most of these difficulties arise in finding reliable matches for pixels in the two images that correspond to the same point in the scene. A further consideration is that stereo analysis for robotics has a real-time constraint, and the processing power needed for some algorithms can be very high. But, in recent years much progress has been made, and the advantage of stereo imaging is that it can provide full 3-D range images, registered with visual information, potentially out to an infinite distance, at high frame rates – something which no other range sensor can match.

Fig. 31.8 Ideal stereo geometry. The global coordinate system is centered on the focal point (camera center) of the left camera. It is a right-handed system, with positive Z in front of the camera, and positive X to the right. The camera principal ray pierces the image plane at C_x, C_y , which is the same in both cameras (a variation for *verged* cameras allows C_x to differ between the images). The focal length is also the same. The images are lined up, with $y = y'$ for the coordinates of any scene point projected into the images. The difference between the x coordinates is called the *disparity*. The vector between the focal points is aligned with the X -axis ►

Fig. 31.7 Range device characteristics (after [31.6]). Spatial precision is on the Y-axis, depth precision on the X-axis. Measurements are taken on a target at 2 m

In this subsection, we will review the basic algorithms of stereo analysis, and highlight the problems and potential of the method. For simplicity, we use binocular stereo.

Stereo Image Geometry

This subsection gives some more detail of the fundamental geometry of stereo, and in particular the relationship of the images to the 3-D world via projection and reprojection. A more in-depth discussion of the geometry and the rectification process can be found in [31.10].

The input images are *rectified*, which means that the original images are modified to correspond to ideal pin-hole cameras with a particular geometry, illustrated in Fig. 31.8. Any 3-D point S projects to a point in the images along a ray through the focal point. If the principal rays of the cameras are parallel, and the images are embedded in a common plane and have collinear scan lines, then the search geometry takes a simple form. The *epipolar line* of a point s in the left image, defined as the possible positions of s' in the right image, is always a scan line with the same y coordinate as s . Thus, search for a stereo match is linear. The process of finding a rectification of the original images that puts them into standard form is called *calibration*, and is discussed in [31.10].

The difference in the x coordinates of s and s' is the *disparity* of the 3-D point, which is related to its distance from the focal point, and the baseline T_x that separates the focal points.

A 3-D point can be projected into either the left or right image by a matrix multiplication in homogenous coordinates, using the *projection matrix*. The 3-D coordinates are in the frame of the left camera (Fig 31.8)

$$\mathbf{P} = \begin{pmatrix} F_x & 0 & C_x & -F_x T_x \\ 0 & F_y & C_y & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}. \quad (31.6)$$

This is the projection matrix for a single camera. F_x and F_y are the focal lengths of the rectified images, and C_x and C_y are the optical center; T_x is the translation of the camera relative to the left (reference) camera. For the left camera, it is 0; for the right camera, it is the baseline times the x focal length.

A point in 3-D is represented by homogeneous coordinates and the projection is performed using a matrix multiply

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \mathbf{P} \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix}, \quad (31.7)$$

where $(x/w, y/w)$ are the idealized image coordinates.

If points in the left and right images correspond to the same scene feature, the depth of the feature can be calculated from the image coordinates using the *repro-*

jection matrix

$$\mathbf{Q} = \begin{pmatrix} 1 & 0 & 0 & -C_x \\ 0 & 1 & 0 & -C_y \\ 0 & 0 & 0 & F_x \\ 0 & 0 & -1/T_x & \frac{(C_x - C'_x)}{T_x} \end{pmatrix}. \quad (31.8)$$

The primed parameters are from the left projection matrix, the unprimed from the right. The last term is zero except for verged cameras. If x, y and x', y are the two matched image points, with $d = x - x'$, then

$$\begin{pmatrix} X \\ Y \\ Z \\ W \end{pmatrix} = \mathbf{Q} \begin{pmatrix} x \\ y \\ d \\ 1 \end{pmatrix}, \quad (31.9)$$

where $(X/W, Y/W, Z/W)$ are the coordinates of the scene feature, and $d = x - x'$ is the disparity. Assuming $C_x = C'_x$, the Z distance assumes the familiar inverse form of triangulation

$$Z = \frac{F_x T'_x}{d}. \quad (31.10)$$

Reprojection is valid only for rectified images – for the general case, the projected lines do not intersect. The disparity d is an *inverse depth* measure, and the vector (x, y, d) is a perspective representation range image (Sect. 31.1.1), sometimes called the *disparity space* representation. The disparity space is often used in applications instead of 3-D space, as a more efficient representation for determining obstacles or other features (Sect. 31.4.3).

Equation (31.9) is a homography between disparity space and 3-D Euclidean space. Disparity space is also useful in translating between 3-D frames. Let $p_0 = [x_0, y_0, d_0, 1]$ in frame 0, with frame 1 related by the rigid motion R, t . From the reprojection (31.9) the 3-D position is $\mathbf{Q}p_0$. Under the rigid motion, this becomes

$$\begin{pmatrix} R & t \\ 0 & 1 \end{pmatrix} \mathbf{Q}p_0,$$

and finally applying \mathbf{Q}^{-1} yields the disparity representation in frame 1. The concatenation of these operations is the homography

$$H(R, t) = \mathbf{Q}^{-1} \begin{pmatrix} R & t \\ 0 & 1 \end{pmatrix} \mathbf{Q}. \quad (31.11)$$

Using the homography allows the points in the reference frame to be directly projected onto another frame, without translating to 3-D points.

Stereo Matching Methods

The fundamental problem in stereo analysis is matching image elements that represent the same object or object part in the scene. Once the match is made, the range to the object can be computed using the image geometry.

Matching methods can be characterized as local or global. Local methods attempt to match small regions of one image to another based on intrinsic features of the region. Global methods supplement local methods by considering physical constraints such as surface continuity or base of support. Local methods can be further classified by whether they match discrete features among images, or correlate a small area patch [31.11]. Features are usually chosen to be lighting and viewpoint independent, for example, corners are a natural feature to use because they remain corners in almost all projections. Feature-based algorithms compensate for viewpoint changes and camera differences, and can produce rapid, robust matching. But they have the disadvantage of requiring perhaps expensive feature extraction, and yielding only sparse range results.

In the next section, we present local area correlation in more detail, since it is one of the most efficient and practical algorithms for real-time stereo. A survey and results of recent stereo matching methods are in [31.12], and the authors maintain a web page listing up-to-date information in [31.13].

Area Correlation Stereo

Area correlation compares small patches among images using correlation. The area size is a compromise, since small areas are more likely to be similar in images with different viewpoints, while larger areas increase the signal-to-noise ratio. In contrast to the feature-based method, area-based correlation produces dense results. Because area methods need not compute features, and have an extremely regular algorithmic structure, they can have optimized implementations.

The typical area correlation method has five steps (Fig. 31.9):

1. Geometry correction. In this step, distortions in the input images are corrected by warping into a *standard form*.
2. Image transform. A local operator transforms each pixel in the grayscale image into a more appropriate form, for example, normalizes it based on average local intensity.
3. Area correlation. This is the correlation step, where each small area is compared with other areas in its search window.
4. Extrema extraction. The extreme value of the correlation at each pixel is determined, yielding a dispar-

Fig. 31.9 Basic stereo processing (see text for details)

ity image: each pixel value is the disparity between the left and right image patches at the best match.

5. Post-filtering. One or more filters clean up noise in the disparity image result.

Correlation of image areas is disturbed by illumination, perspective, and imaging differences among images. Area correlation methods usually attempt to compensate by correlating not the raw intensity images, but some transform of the intensities. Let u, v be the center pixel of the correlation, d the disparity, and $I_{x,y}, I'_{x,y}$ the intensities of the left and right images:

1. Normalized cross-correlation

$$\frac{\sum_{x,y} [I_{x,y} - \hat{I}_{x,y}] [I'_{x-d,y} - \hat{I}'_{x-d,y}]}{\sqrt{\sum_{x,y} [I_{x,y} - \hat{I}_{x,y}]^2 \sum_{x,y} [I'_{x-d,y} - \hat{I}'_{x-d,y}]^2}}$$

2. High-pass filter such as Laplacian of Gaussian (LOG). The Laplacian measures directed edge intensities over some area smoothed by the Gaussian. Typically, the standard deviation of the Gaussian is 1–2 pixels

$$\sum_{x,y} s(\text{LOG}_{x,y} - \text{LOG}_{x-d,y}),$$

where $s(x)$ is x^2 or $||x||$.

3. Nonparametric. These transforms are an attempt to deal with the problem of outliers, which tend to overwhelm the correlation measure, especially using a square difference. The census method [31.14] computes a bit vector describing the local environment of a pixel, and the correlation measure is the Hamming distance between two vectors

$$\sum_{x,y} (I_{x,y} > I_{u,v}) \oplus (I'_{x-d,y} > I'_{u,v}).$$

Results on the different transforms and their error rates for some standard images are compiled in [31.13].

Another technique for increasing the signal-to-noise ratio of matches is to use more than two images [31.15].

Table 31.2 Post-filtering techniques for eliminating false matches in area correlation

Correlation surface [31.17]	Peak width: Wide peak indicates poor feature localization Peak height: Small peak indicates poor match Number of peaks: Multiple peaks indicate ambiguity
Mode filter	Lack of supporting disparities violates smoothness
Left/right check [31.18, 19]	Nonsymmetric match indicates occlusion
Texture [31.20]	Low texture energy yields poor matches

This technique can also overcome the problem of view-point occlusion, where the matching part of an object does not appear in the other image. The simple technique of adding the correlations between images at the same disparity seems to work well [31.16]. Obviously, the computational expenditure for multiple images is greater than that for two.

Dense range images usually contain false matches that must be filtered, although this is less of a problem with multiple-image methods. Table 31.2 lists some of the post-filters that have been discussed in the literature.

Disparity images can be processed to give subpixel accuracy, by trying to locate the correlation peak between pixels. This increases the available range resolution without much additional work. Typical accuracies are 1/10 pixel.

Stereo Range Quality
Various artifacts and problems affect stereo range images.

Smearing. Area correlation introduces expansion in foreground objects, for example, the woman’s head in Fig. 31.10. The cause is the dominance of strong edges on the object. Nonparametric measures are less subject to this phenomenon. Other approaches include multiple correlation windows and shaped windows.

Dropouts. These are areas where no good matches can be found because of low texture energy. Dropouts are a problem for indoor and outdoor man-made surfaces. Projecting a random texture can help [31.21].

Range Resolution. Unlike LADAR devices, stereo range accuracy is a quadratic function of distance, found by differentiating (31.10) with respect to disparity

$$\delta Z = -\frac{F_x T'_x}{d^2} . \tag{31.12}$$

The degradation of the stereo range with distance can be clearly seen in the 3-D reconstruction of Fig. 31.10.

Processing. Area correlation is processor-intensive, requiring Awd operations, where A is the image area, w is the correlation window size, and d is the number of disparities. Clever optimizations take advantage of redundant calculations to reduce this to Ad (independent of window size), at the expense of some storage. Real-time implementations exist for standard personal computers (PC)s [31.22, 23], graphics accelerators [31.24, 25], digital signal processors (DSPs) [31.26], field programmable gate arrays (FPGAs) [31.22, 27], and specialized application-specific integrated circuits (ASICs) [31.28].

Other Visual Sources of Range Information
Here we briefly list the most popular, but less reliable sources of range information. These sources can potentially supplement other sensors:

- **Focus/defocus:** Knowledge of the camera parameters and the amount of blur of image features allows the estimation of how far the corresponding scene features are from the perfect focus distance [31.29]. Sensors may be passive (using a precaptured image) or active (capturing several images with different focus settings).

Fig.31.10a–c Sample stereo results from an outdoor garden scene; baseline is 9 cm. (a) original left image. (b) computed 3-D points from a different angle. (c) disparity in pseudo-color

- **Structure and motion:** Structure and motion algorithms compute 3-D scene structure and the sensor positions simultaneously [31.30]. This is essentially a binocular stereo process (see discussion before), except that only a single moving camera is used. Thus, the images needed by the stereo process are acquired by the same camera in several different positions. Video camcorders are also used, but they have lower resolution. One important advantage of this approach over the normal algorithm is that features can be tracked easily if the time between frames or the motion is small enough. This simplifies the *correspondence problem*; however, it can lead to another problem. If the pair of images used for the stereo calculation are taken close together in time, then the separation between the cameras' images will not be much – this is a *short baseline*. Triangulation calculations are then more inaccurate, as small errors in estimating the position of image features results in large errors in the estimated 3-D position (particularly the depth estimate). This problem can be partly avoided by tracking for longer periods. A second problem that can arise is that not all motions are suitable for estimate of the full 3-D scene structure. For example, if the video recorder only rotates about its optical axis or about its focus point, then no 3-D information can be recovered. A little care can avoid this problem.
- **Shading:** The pattern of shading on a surface is related to the orientation of the surface relative to the observer and light sources. This relationship can be used to estimate the surface orientation across the surface. The surface normals can then be integrated to give an estimate of the relative surface depth.
- **Photometric stereo:** Photometric stereo [31.31] is a combination of shading and stereo processes. The key concept is that the shading of an object varies with the position of the light sources. Hence, if you had several aligned pictures of an object or scene with the light source in different positions (e.g., the sun moved), then you can calculate the scene's surface normals. From these, the relative surface depth can be estimated. The restriction of a stationary observer and changing light sources makes this approach less likely to be useful to most robotics applications.
- **Texture:** The way uniform or statistical textures vary on a surface is related to the orientation of the surface relative to the observer. As with shading, the texture gradients can be used to estimate the surface orientation across the surface [31.32]. The surface

normals can then be integrated to give an estimate of the relative surface depth.

31.2.5 Structured Light Stereo

Recently, the Kinect range-sensing device became the fastest-selling consumer electronics device in history [31.33]. The Kinect uses a structured-light stereo technique from PrimeSense (bought out by Apple, Inc.) to give a reasonable balance of spatial and depth precision, in a highly-integrated device, at a very low price.

The PrimeSense technology projects a structured pattern generated from an IR (infrared) laser and patented combination of diffractive elements (Fig. 31.11). The pattern consists of bright dots on a grid, with unique combinations of dots over a horizontal area. A camera with resolution 1280×960 captures the IR image at a horizontal offset of 7.5 cm from the projector, and correlates a 19×19 block against the known dot pattern for a given horizontal line. If a match is found, the position of the pattern in the known projected pattern gives the angle subtended by the reflecting object to the projector and camera, and hence the distance. A depth image is returned at a resolution of 640×480 , with 11 bits of depth precision, over an FOV of approximately 50° ; the depth is interpolated to a precision of $1/8$ pixel. Error characteristics for the Kinect have been studied in [31.34]. The depth decision is limited by the resolution, similarly to (31.3).

There are additional sources of error. *Dropouts* occur when the surfaces are minimally reflective, or specular. *False positives*, where there are gross mismatches in the match, are very rare with PrimeSense technology. *Spatial precision* is much lower than the returned 640×480 depth image would indicate, because of the *smear-*

Fig. 31.11 The laser grid of the Kinect for calculating depth

ing effect of block correlation. The projected pattern expands and contracts based on temperature, leading to offset in disparities along the vertical axis. While the projector is temperature controlled via a Peltier unit, its

temperature can vary. A temperature sensor measures this variation, and applies disparity steps across the image, which are apparent as vertical steps in the depth image.

31.3 Registration

This section introduces techniques for 3-D localization of parts for robot manipulation, self-localization of robot vehicles, and scene understanding for robot navigation. All of these are based on the ability to register 3-D shapes, for example, range images to range images, triangulated surfaces or geometric models. Registration puts two or more independently acquired 3-D shapes into one frame of reference. It can be solved as an optimization problem that uses a cost function for the quality of the alignment. The 3-D shapes are registered by determining the rigid transformation (rotation and translation) which minimizes the cost function. Feature based registration extracts distinguishing features of the range images and uses corresponding features for calculating the alignment.

31.3.1 The ICP Algorithm

The following method is used for the registration of point sets. The complete algorithm was invented at the same time in 1991 by *Besl* and *McKay* [31.35], by *Chen* and *Medioni* [31.36], and by *Zhang* [31.37]. The method is called iterative closest points (ICP) algorithm. It is the de-facto standard for registration of point sets, but is also applicable to 3-D shapes, if one samples them.

Given two independently acquired sets of 3-D points, \hat{M} (model set) and \hat{D} (data set) which correspond to a single shape, we want to find the transformation (\mathbf{R}, \mathbf{t}) consisting of a rotation matrix \mathbf{R} and a translation vector \mathbf{t} which minimizes the following cost function,

$$E(\mathbf{R}, \mathbf{t}) = \frac{1}{N} \sum_{i=1}^N \|\mathbf{m}_i - (\mathbf{R}\mathbf{d}_i + \mathbf{t})\|^2. \quad (31.13)$$

All the corresponding points can be represented in a tuple $(\mathbf{m}_i, \mathbf{d}_i)$ where $\mathbf{m}_i \in M \subset \hat{M}$ and $\mathbf{d}_i \in D \subset \hat{D}$. Two things have to be calculated. First, the corresponding points, and second, the transformation (\mathbf{R}, \mathbf{t}) that minimizes $E(\mathbf{R}, \mathbf{t})$ on the basis of the corresponding points. The ICP algorithm uses closest points as corresponding points. A sufficiently good starting guess enables the ICP algorithm to converge to the correct minimum. Figure 31.12 shows two 3-D point clouds, their initial alignment and the final registration after a few ICP iterations.

Implementations of ICP (Algorithm 31.1) use a maximal distance for closest points to handle partially overlapping point sets. In this case, the proof about ICP's monotonic convergence in [31.35] no longer holds, since the number of points as well as the value of $E(\mathbf{R}, \mathbf{t})$ might increase after applying a transformation.

Algorithm 31.1 The ICP algorithm

- 1: **for** $i = 0$ to $maxIterations$ **do**
- 2: **for all** $\mathbf{d}_j \in D$ **do**
- 3: find the closest point within a range d_{max} in the set M for point \mathbf{d}_j
- 4: **end for**
- 5: Calculate transformation (\mathbf{R}, \mathbf{t}) that minimizes the error function (31.13)
- 6: Apply the transformation found in step 5 to the data set D .
- 7: Compute the difference of the quadratic error, that is, compute the difference of the value $\|E_{i-1}(\mathbf{R}, \mathbf{t}) - E_i(\mathbf{R}, \mathbf{t})\|$ before and after the ap-

Fig. 31.12a,b Initial alignment of two 3-D point clouds (a) and after optimization with ICP (b)

plication of the transformation. If this difference falls below a threshold ε , terminate.

8: **end for**

Current research in the context of **ICP** algorithms mainly focuses on fast variants of **ICP** algorithms [31.38]. If the input are 3-D meshes then a point-to-plane metric can be used instead of (31.13). Minimizing using a point-to-plane metric outperforms the standard point-to-point one, but requires the computation of normals and meshes in a preprocessing step.

The computation of closest points is the crucial step of the **ICP** algorithm. A naive implementation examines all points in \hat{M} and the resulting computation time for **ICP** is $O(|\hat{D}||\hat{M}|)$, that is, $O(n^2)$. Note that \hat{N} can be very large; advanced high-precise 3-D laser scanners such as the Zoller + Fröhlich yield a data rate up to 1 000 000 3-D points per second. An efficient tree data structure, a k -d tree, is widely used to speed up the closest point computation. Every node of the k -d tree represents a partition of the point set into two distinct sets, the successor nodes. The root of the tree represents the whole point set. The leaves of the tree are called buckets and are a partition of the set into small, disjunctive point sets. Furthermore, every node of the tree consists of the center and the dimension of the point set. In the original k -d tree paper, these so-called split dimensions have been chosen depending on the depth of node in a robin-round fashion [31.39]. The split dimension and value define an axis-aligned hyperplane in the k -dimensional space. The data are partitioned according to their position to the hyperplane into the successor nodes. The k -d tree is constructed until the number of points in the nodes falls below a threshold b (bucket size). Only the leaves of the tree contain the data points. Searching in k -d trees is done recursively. A given 3-D point p_q needs to be compared to the separating plane (splitting dimension and splitting value) in order to decide on which side the search must continue. This procedure is executed until the leaves are reached. There, the algorithm has to evaluate all bucket points. However, the closest point may be in a different bucket, iff the distance d of the query point p_q to the limits is smaller than the one to the closest point in the bucket p_b . In this case backtracking has to be performed. The test is known as Ball-Within-Bounds test [31.39–41]. The optimized k -d tree chooses the split dimension and split value [31.40], such that the expected amount of backtracking is minimized. Since one typically has no information about the query points k -d tree algorithms take only the distribution of the given points into account. For all possible queries, this works

sufficiently, but it will not be optimal for a specific query [31.40]. This enables the recursive construction and avoids the overall optimization that is known to be NP-complete [31.42].

Improvements to k -d tree search, especially for small dimensions, have been shown in the last decade. They include approximate k -d tree search [31.41], registration using d^2 -trees [31.43] and cached k -d tree search [31.44]. In addition, the spatial data structure octree might, which is discussed later in this section, can be used to search the point clouds with similar performance.

In each **ICP** iteration, the transformation can be calculated in $O(N)$ by any of these four methods:

1. A singular value decomposition (**SVD**)-based method by *Arun et al.* [31.45]
2. A quaternion-based method by *Horn et al.* [31.46]
3. An algorithm using orthonormal matrices by *Horn* [31.47]
4. A calculation based on dual quaternions by *Walker et al.* [31.48]. Besides these closed-form solutions, there are several linearized, approximative version [31.49].

The challenge is to ensure that \mathbf{R} is orthonormal. Most often, the first method is implemented, due to its simplicity and the availability of numerical **SVDs** in various libraries. The rotation \mathbf{R} is represented as an orthonormal 3×3 matrix. The optimal rotation is calculated by $\mathbf{R} = \mathbf{V}\mathbf{U}^T$. Here the matrices \mathbf{V} and \mathbf{U} are derived by the **SVD** $\mathbf{H} = \mathbf{U}\mathbf{\Lambda}\mathbf{V}^T$ of a cross-correlation matrix \mathbf{H} . This 3×3 matrix \mathbf{H} is given by

$$\mathbf{H} = \sum_{i=1}^N \mathbf{m}_i' \mathbf{d}_i' = \begin{pmatrix} S_{xx} & S_{xy} & S_{xz} \\ S_{yx} & S_{yy} & S_{yz} \\ S_{zx} & S_{zy} & S_{zz} \end{pmatrix}, \quad (31.14)$$

where

$$S_{xx} = \sum_{i=1}^N m'_{x,i} d'_{x,i}, S_{xy} = \sum_{i=1}^N m'_{x,i} d'_{y,i}, \dots$$

31.3.2 Marker and Feature-Based Registration

To avoid issues with starting guess in the **ICP** framework, marker-based registration uses defined artificial or natural landmarks as corresponding points. This manual data association ensures that by minimizing (31.13) the scans are registered at the correct location. Iterations are no longer required, but possible as verification with the **RANSAC** algorithm. The **RANSAC** algorithm is a general, randomized procedure that iter-

actively finds an accurate model for observed data that may contain a large number of outliers [31.50].

3-D Feature Representations and Extraction

There are many representations available for encoding 3-D scene structure and model representations, but the following representations are the ones most commonly encountered in robotics applications. Some scene models or descriptions may use more than one of these simultaneously to describe different aspects of the scene or object models.

Normals. Normals describe the surface orientation in a points. There are a number of approaches that have been developed for computing normals in point clouds and range images. Most of these approaches involves some form of eigenvalue decomposition resembling total linear least squares. The normals are usually computed when taking into account the nearby neighbor points which are computed using a variety of methods like nearest neighbor search. These methods include k nearest neighbors (k -NN) and radius search among others. The method of total least squares is robust to noise as it inherently includes low-pass filtering, but it is sensitive to the distribution and density of the point samples as well as the curvature of the underlying manifold. Improvements to the above method by using higher order surfaces are discussed in [31.51] and it is noted that such methods can fail even with arbitrarily dense samples.

The total least-squares problem finds the plane parameters that optimally fit a small surface area in a point set given by the the nearest neighbors. A plane is defined by

$$n_x x + n_y y + n_z z - d = 0 ,$$

where $\mathbf{p} = (x, y, z)^T$ lies on the plane and (n_x, n_y, n_z, d) are the parameters to compute. Given a subset of k 3-D points $\mathbf{p}_i, i = 1, 2, \dots, k$ of the surface, least squares finds the optimal normal vector $\mathbf{n} = (n_x, n_y, n_z)^T$ and scalar d that minimizes the following error equation

$$e = \sum_{i=1}^k (\mathbf{p}_i \mathbf{n} - d) . \quad (31.15)$$

The basic method for normal estimation from the neighboring points using a fitting plane is the principal component analysis (PCA). PCA is the eigenvalue decomposition of the data covariance (or correlation) matrix or singular value decomposition of a data matrix, usually after mean centering (and normalizing) the data matrix for each attribute (3-D query point). PCA

can be interpreted as fitting a Gaussian distribution and computing the main axes. For each query point

$$\begin{aligned} \boldsymbol{\mu} &= \frac{1}{k} \sum_{i=1}^k \mathbf{p}_i , \\ \boldsymbol{\Sigma} &= \frac{1}{k} \sum_{i=1}^k (\mathbf{p}_i - \boldsymbol{\mu})^T (\mathbf{p}_i - \boldsymbol{\mu}) . \end{aligned}$$

The vector corresponding to the smallest eigenvalue of the above matrix $\boldsymbol{\Sigma}$ is the normal direction if the neighboring points belong to a plane and this is also the closed form solution of the total least-squares problem.

For equirectangular range images, that is, spherical coordinates, a fast algorithm has been developed in [31.52] that avoids computing eigenvalues. Dividing (31.15) by d^2 gives a simplified function and further division by the squared range ρ^2 yields

$$\begin{aligned} e &= \sum_{i=1}^k ((\rho^{-1} \mathbf{p}_i)^T \mathbf{n} - \rho_i^{-1})^2 , \\ \mathbf{p}_i &= \begin{pmatrix} \cos \theta_i \sin \varphi_i \\ \sin \theta_i \sin \varphi_i \\ \cos \varphi_i \end{pmatrix} . \end{aligned}$$

Therefore, a solution for \mathbf{n} is given as

$$\mathbf{n} = \mathbf{M}^{-1} \mathbf{b} ,$$

where

$$\mathbf{M} = \sum_{i=1}^k \mathbf{p}_i \mathbf{p}_i^T , \mathbf{b} = \sum_{i=1}^k \frac{\mathbf{p}_i}{\rho_i} .$$

This way the computation of eigenvalues is avoided and the matrix \mathbf{M} can be precomputed for the desired image coordinates as it does not depend on the range. The tangential surface and therefore its normal vector are obtained by simply taking the derivative of the surface function in the point of interest

$$\begin{aligned} \mathbf{n} &= \nabla \rho = \nabla \rho(\theta, \varphi) \\ &= \begin{pmatrix} \cos \theta \sin \theta - \frac{\sin \theta}{\rho \sin \varphi} \frac{\partial \rho}{\partial \theta} + \frac{\cos \theta \cos \varphi}{\rho} \frac{\partial \rho}{\partial \varphi} \\ \sin \theta \sin \theta - \frac{\cos \theta}{\rho \sin \varphi} \frac{\partial \rho}{\partial \theta} + \frac{\sin \theta \cos \varphi}{\rho} \frac{\partial \rho}{\partial \varphi} \\ \cos \varphi - \frac{\sin \varphi}{\rho} \frac{\partial \rho}{\partial \varphi} \end{pmatrix} . \end{aligned}$$

3-D Point Features. This is a set $\{\mathbf{p}_i = (x_i, y_i, z_i)\}$ of 3-D points that describe some salient and identifiable points in the scene. They might be the centers of spheres (often used as markers), corners where three planes

intersect, or the extrema of some protrusion or indentation on a surface. They may be a subset of an initially acquired 3-D full scene point set, or they might be extracted from a range image, or they might be computed theoretical points based on extracted data features.

An early example of 3-D point features and descriptors are spin images, which are used for surface matching between point clouds and meshes. Scanned 3-D points become the vertices of the mesh and connectivity is established by the 3-D scanning geometry. A fundamental component of the surface matching representation is an oriented point, a three-dimensional point with an associated direction. Huber et al. define an oriented point O at a surface mesh vertex using the 3-D position of the vertex p and the surface normal at the vertex n [31.53]. Two coordinates can be calculated given an oriented point: α the radial distance to the surface normal line L and β the axial distance above the tangent plane P (Fig. 31.13).

$$\begin{aligned} (x) &\mapsto (\alpha, \beta) \\ &= \left(\sqrt{\|x - p\|^2 - [n \cdot (x - p)]^2}, n \cdot (x - p) \right) \end{aligned}$$

The term spin map originates from the cylindrical symmetry of the oriented point basis; the basis can spin about its axis with no effect on the coordinates of points with respect to the basis [31.53]. A consequence of the cylindrical symmetry is that points that lie on a circle that is parallel to P and centered on L will have the same coordinates (α, β) with respect to the basis.

Seminal work on 3-D point features are the point feature histogram (PFH) descriptors. They encode a point's k -neighborhood geometrical properties by generalizing the mean curvature around the point using a multidimensional histogram of values [31.54]. This highly dimensional hyperspace aims at providing an informative signature for the feature representation, being invariant to the six-dimensional (6-D) pose of the underlying surface, and coping very well with different sampling densities or noise levels present in the neighborhood [31.55].

Fig. 31.13 Definition of a spin image

To formulate the new feature space, the concept of a dual-ring neighborhood is first introduced. Following the notation and the text of [31.54], let P be a set of 3-D points with x_i, y_i, z_i being the geometric coordinates. A point p_i of P is said to have a dual-ring neighborhood if

$$r_1, r_2 \in Rr_1 < r_2, \text{ such that } \begin{cases} r_1 \rightarrow P^{k_1} \\ r_2 \rightarrow P^{k_2} \end{cases},$$

with $0 < k_1 < k_2$. The two radii r_1 and r_2 are used to determine two distinct layers of feature representations for p_i . The first layer represents the surface normal at the query point from the neighborhood patch P^{k_1} . The second layer comprises the PFH as a set of angular features (Fig. 31.14)

$$\begin{aligned} \alpha &= v \cdot n_t, \\ \varphi &= u \cdot \frac{(p_t - p_s)}{d}, \\ \theta &= \arctan(w \cdot n_t, u \cdot n_t). \end{aligned}$$

In addition to 3-D structural features, 3-D features derived from texture, for example, coregistered color images or scan reflectivities, are widely used for registration [31.56, 57]. Figure 31.15 shows scale invariant feature transform (SIFT) features extracted from a 3-D scanner with calibrated reflectivity values.

Fig. 31.15 Sift features extracted from the reflectivity values of a 3-D laser scan

Planes. A planar surface may only be described by the infinite surface as given by the equation, but it may also include a description of the boundary of the surface patch. Convenient representations for robotics applications are lists of the 3-D points $\{(x_i, y_i, z_i)\}$ that form the patch boundary, or polylines, which represent the boundary by a set of connected line segments. A polyline is represented by the sequence of 3-D points $\{(x_i, y_i, z_i)\}$ that form the vertices that join the line segments.

Plane extraction, or plane fitting, is the problem of modeling a given 3-D point cloud as a set of planes that ideally explain every data point. The RANSAC algorithm is one possible algorithm. When adapted for plane finding, this algorithm selects three 3-D points at random (although exploiting some locality to the point selection algorithm can improve the efficiency of the algorithm). These three points determine a plane with a parameter vector \mathbf{a} . Test all points $\{\mathbf{p}\}$ in the set for belonging to the plane ($|\mathbf{p}_i \cdot \mathbf{a}| < \tau$). If enough points are close to the plane, then potentially a plane has been found. These points should also be processed to find a connected set, from which a more accurate set of plane parameters can be estimated using the least-squares algorithm given above. If a planar patch is successfully found, the points that lie in that plane are removed from the dataset. The random selection of three points then continues until no more planes are found (a bound on how many tries to make can be estimated). For example, Schnabel et al. [31.58] have adapted RANSAC for plane extraction and found that the algorithm performs precise and fast plane extraction, but only if the parameters have been fine-tuned properly. For their optimization, they use information, which is not readily available in point cloud data, such as normals, neighboring relations, and outlier ratios.

A further standard method for plane detection is region growing, based on a seed patch. When the scene largely consists of planes, a particularly simple approach is based on selecting a previously unused point and the set of points $\{\mathbf{p}_i = (x_i, y_i, z_i)\}$ in its neighborhood. A plane is fit to these points using the least-squares method (cf. normal computation). This hypothesized plane then needs to be tested for reasonableness by 1) examining the smallest eigenvalue – it should be small and of the order of the square of the expected noise level and 2) ensuring that most of the 3-D points in the fitted set lie on the plane ($|\mathbf{p}_i \cdot \mathbf{a}| < \tau$).

Larger planar regions are *grown* by locating new adjacent points \mathbf{p}_i that lie on the plane ($|\mathbf{p}_i \cdot \mathbf{a}| < \tau$). When enough of these are found, the parameters \mathbf{a} of the plane are re-estimated. Points on the detected plane are removed and the process is repeated with a new seed patch. This process continues until no more points can be added. Complete descriptions of planar feature extraction with region growing are given in [31.59].

Bauer and Polthier use the radon transform to detect planes in volume data [31.60]. The idea and the speed of the algorithm are similar to that of the standard Hough transform. The Hough transform [31.61] is a method for detecting parametrized objects. For the Hough transform, planes are represented in the Hesse normal form, using normal vectors. A plane is thereby given by a point \mathbf{p} on the plane, the normal vector \mathbf{n} that is perpendicular to the plane and the distance ρ to the origin

$$\rho = \mathbf{p} \cdot \mathbf{n} = p_x n_x + p_y n_y + p_z n_z = \rho.$$

Considering the angles between the normal vector and the coordinate system, the coordinates of \mathbf{n} are factorized to

$$p_x \cdot \cos \theta \cdot \sin \varphi + p_y \cdot \sin \varphi \cdot \sin \theta + p_z \cdot \cos \varphi = \rho, \quad (31.16)$$

with θ is the angle of the normal vector on the xy -plane and φ the angle between the xy -plane and the normal vector in the z direction. φ , θ , and ρ define the 3-dimensional Hough space (θ, φ, ρ) such that each point in the Hough space corresponds to *one plane* in \mathbb{R}^3 . To find planes in a point set, one calculates the Hough transform for each point. Given a point \mathbf{p} in Cartesian coordinates, one finds all planes the point lies on, that is, find all the θ , φ , and ρ that satisfy (31.16). Marking these points in the Hough space, that is, leads to a 3-D sinusoid curve as shown in Fig. 31.16. The intersections of two curves in the Hough space denote the planes that are rotated around the line built by the two points. Consequently, the intersection of three curves

Fig. 31.16 Transformation of three points from \mathbb{R} to the Hough space (θ, φ, ρ) . The intersection of the curves (marked in black) depicts the plane spanned by the three points

in the Hough space corresponds to the polar coordinates defining the plane spanned by the three points. In Fig. 31.16, the intersection is marked in black. Given a set P of points in Cartesian coordinates, one transforms all points $p_i \in P$ into the Hough space. The more curves intersect in $h_j \in (\theta, \varphi, \rho)$, the more points lie on the plane represented by h_j and the higher is the probability that h_j is actually extracted from P .

The standard Hough transform is far too slow for plane detection in real-world data. A variant called randomized Hough transform is the method of choice when dealing with 3-D data due to its exceptional performance as far as runtime and quality are concerned [31.62].

Other plane extraction algorithms are highly specialized for a specific application and are not in widespread use for miscellaneous reasons. *Lakaemper* and *Latecki* [31.63] used an expectation maximization (EM) algorithm to fit planes that are initially randomly generated, *Wulf* et al. [31.64] detected planes relying on the specific properties of a sweeping laser scanner and *Yu* et al. [31.65] developed a clustering approach to solve the problem.

Triangulated Surfaces. Most commonly, surfaces are approximated by polygonal meshes, particularly tri-

angle meshes, a standard data structure in computer graphics to represent 3-D objects. This representation describes an object or scene by a set of triangular patches. More general polygonal surface patches or even various smooth surface representations are also used, but triangles are most commonly used because they are simpler and there are inexpensive PC graphics cards that display triangles at high speed.

The triangles can be large (e.g., when representing planar surfaces) or small (e.g., when representing curved surfaces). The size chosen for the triangles reflects the accuracy desired for representing the object or scene surfaces. The triangulated surface might be complete in the sense that all observable scene or objects surfaces are represented by triangles, or there might be disconnected surface patches with or without internal holes. For grasping or navigation, you do not want any unrepresented scene surface to lie in front of the represented portion of the surface where a gripper or vehicle might collide with it. Hence, we assume that the triangulation algorithms produce patch sets that, if completely connected at the edges, implicitly bound all real scene surfaces. Figure 31.17 shows an example of a triangulated surface and the original point cloud.

The de-facto standard is the marching cubes method introduced by *Lorensen* and *Cline* [31.66]. This algorithm subdivides the scanned volume into cubic cells or voxels. For each cell, the intersections between the cell edges and the surface are calculated. Precalculated surface patterns are then used to generate a local triangle mesh approximation. An example of such patterns are given in Fig. 31.18. To interpolate the intersections, implicit continuous surface representations like planes or splines are fitted to the local data using least-squares fits [31.67, 68]. A feature of the marching cubes algorithm is that it produces more triangles than are needed to represent an object. Hence, several mesh simplification algorithms have been introduced over the past years. Most of them define error metrics that indicate the error that a certain operation causes to the model, that is, the removal of an edge [31.69, 70]. To optimize the model, the edges causing the minimal error to the

Fig. 31.17 (a) Image acquired with a kinect-like sensor. (b) Reconstruction with kinect fusion

Fig. 31.18 Pattern for meshing 3-D voxels. 256 combinations are possible, but it is sufficient to model 16, iff symmetries are considered

topology are removed iteratively. Since after each edge removal new vertices have to be inserted into the mesh, the initial topology can be altered.

The Kinect fusion approach modifies Hoppe's distance function [31.71]. It exploits the properties of the depth image (rectangular) to calculate normals and the associated planes. The method is massively parallelized by a GPU (graphics processing unit) implementation and can reconstruct and register meshes in real time.

3-D Lines. The 3-D lines where planar surfaces meet are features that can be easily detected by both stereo and range sensors. These features occur commonly in built environments (e.g., where walls, floors, ceilings, and doorways meet, around the edges of wall structures like notice boards, at the edges of office and warehouse furniture, etc.). They are also common on manmade objects. In the case of stereo, changes of surface shape or coloring are detected as edges, which can be matched in the stereo process to directly produce the 3-D edge. In the case of a range sensor, planar surfaces can be easily extracted from the range data (see the next section) and adjacent planar surfaces can be intersected to give the edges.

The most straightforward representation for 3-D lines is the set of points $\mathbf{x} = \mathbf{p} + \lambda \mathbf{v}$ for all λ , where \mathbf{v} is a unit vector. This has 5 degrees of freedom; more

complex representations for example, with 4 degrees of freedom exist [31.10].

Voxels. The voxel (volume pixel) approach represents the 3-D world by 3-D boxes/cells that indicate where there is a scene structure and where there is free space. The simplest representation is a 3-D binary array, encoded as 1 for having a structure and 0 for free space. This can be quite memory intensive, and also requires a lot of computation to check many voxels for content. A more complex but more compact representation is the hierarchical representation called the octree [31.72]. This divides the entire (bounded) rectangular space into eight rectangular subspaces called octants (Fig. 31.19). A tree data structure encodes the content of each octant as empty, full or mixed. Mixed octants are then subdivided into eight smaller rectangular octants, encoded as subtrees of the larger tree. Subdivision continues until some minimum octant size is reached. Determining whether a voxel is empty, full, or mixed depends on the sensor used, however, if no 3-D data points are located in the volume of a voxel, then it is likely to be empty. Similarly, if many 3-D points are present, then the voxel is likely to be full. Currently, many implementations using octrees for range data are available [31.73, 74]. Furthermore, these voxel representations are the basis of surface/mesh reconstruction algorithms as described earlier.

For the purpose of robot navigation, localization or grasping, only the surface and free-space voxels need to be marked accurately. The interior of objects and scene structure are largely irrelevant.

Straight Lines. While straight lines are common in man-made scenes, direct extraction from 3-D datasets is not easy. The main source of the difficulty is that the 3-D sensors often do not acquire good responses at edges of surfaces. For this reason, most 3-D line detection algorithms are indirect, whereby planes are first detected, for example, using the method of the previous section, and then adjacent planes are intersected. Adjacency can be tested by finding paths of connected pixels that lead from one plane to the other. If planes 1 and 2 contains points p_1 and p_2 and have surface normals n_1 and n_2 , respectively, then the resulting intersection line has equation $x = a + \lambda d$ where a is a point on the line and $d = \frac{n_1 \times n_2}{\|n_1 \times n_2\|}$ is the line direction.

There are an infinite number of possible points a , which can be found by solving the equations $a'n_1 = p'_1n_1$ and $a'n_2 = p'_2n_2$. A reasonable third constraint that obtains a point near p_2 is the equation $a'd = p'_2d$. This gives us an infinite line. Most practical applications require a finite segment. The endpoints can be estimated by (1) finding the points on the line that lie close to observed points in both planes and then (2) finding the two extremes of those points. On the other hand, finding straight 3-D lines can be easier with a stereo sensor, as these result from matching two straight 2-D image lines.

31.3.3 Multiple-View Registration

A globally consistent representation of a robot's environment is crucial for many robotic applications. Equipped with a 3-D depth-perceiving sensor, many mobile systems gather spatial information about their

Fig. 31.19 (a) Spatial subdivisions of an octree up to level 3. Occupied leaf nodes are shaded grey. (b) The corresponding tree structure of the sparse data structure

local 3-D environments. Any iterative application of matching algorithms leads to inconsistencies due to sensing errors and due to the inaccuracies in the matching procedures itself. To avoid these problems, global matching algorithms are needed, taking global correspondences between range sensor data into account. Simultaneous localization and mapping (SLAM) algorithms as discussed in Chap. 46 solve a very similar problem. In addition to registering multiple views, they estimate a map. Multiple-view registration also relates to bundle adjustment in the photogrammetry community and structure from motion (SfM).

If n -views have to be registered, any sequential application of a two point-set registration method will accumulate errors, and therefore the registration algorithm (Sect. 31.3.1) has to be extended. The global error function becomes

$$E = \sum_{l \rightarrow k} \sum_i \|(\mathbf{R}_l \mathbf{m}_{l,i} + \mathbf{t}_l) - (\mathbf{R}_k \mathbf{d}_{k,i} + \mathbf{t}_k)\|^2, \quad (31.17)$$

where all views have their unique pose (\mathbf{R}, \mathbf{t}) . After the point pairs for all overlapping views (l, k) have been found, (31.17) is minimized. Unfortunately, a closed-form solution for minimizing (31.17) is not known, but a small angle approximation or the helix transform yield a system of linear equations that can be solved by Cholesky decomposition [31.49]. In an ICP-like fashion after every transformation new point pairs have to be found (Algorithm 31.2).

Algorithm 31.2 The globally consistent ICP algorithm

- 1: **for** $i = 0$ to $maxIterations$ **do**
- 2: find the closest point within a range d_{max} of every pair of overlapping 3-D point clouds (l, k) .
- 3: Calculate n transformations (\mathbf{R}, \mathbf{t}) simultaneously that minimize the error function (31.17)
- 4: Apply the n transformations found in step 4 to all data sets.
- 5: Compute the difference of the quadratic error, that is, compute the difference of the value $\|E_{i-1} - E_i\|$ before and after the application of the transformation. If this difference falls below a threshold ε , terminate.
- 6: **end for**

A probabilistic SLAM-like notation of (31.17) was formulated in [31.75] for 2-D range scans. For each pose X , the term \tilde{X} denotes a pose estimate, and ΔX is the pose error. The positional error of two poses X_i

and X_k is described by

$$E_{j,k} = \sum_{i=1}^m \|X_j \oplus d_i - X_k \oplus m_i\|^2.$$

Here, \oplus is the compounding operation that transforms a point into the global coordinate system. For small pose differences, $E_{j,k}$ can be linearized by using a Taylor expansion. With the linearized error metric $E'_{j,k}$ and the Gaussian distribution $(\bar{E}_{j,k}, C_{j,k})$ a Mahalanobis distance that describes the global error of all the poses is constructed

$$\begin{aligned} W &= \sum_{j \rightarrow k} (\bar{E}_{j,k} - E'_{j,k})^T C_{j,k}^{-1} (\bar{E}'_{j,k} - E'_{j,k}) \\ &= \sum_{j \rightarrow k} [\bar{E}_{j,k} - (X'_j - X'_k)] C_{j,k}^{-1} [\bar{E}'_{j,k} - (X'_j - X'_k)], \end{aligned} \quad (31.18)$$

which can be solved efficiently using iterative least squares techniques, for example, Levenberg–Marquadt or conjugate gradient methods [31.76, 77]. The covariances are computed from point pairs. In the presence of correct covariances, (31.18) is minimized once. In case of scan matching, new pose estimates yield new closest point pairs and in turn new covariances. Iterating the process of calculating point pairs and minimization yields a stable algorithm that converges rapidly. The probabilistic notation and the global ICP notation are very similar [31.49]. The solution for 2-D range scans has been extended to 6-DOF in [31.78].

31.3.4 Model Matching

Model matching is the process of matching some stored representation to some observed data. In the case discussed here, we assume that both are 3-D representations. Furthermore, we assume that the representations being matched are both of the same type, for example, 3-D model and scene lines. (While different types of data can also be matched, we ignore these more specialized algorithms here.)

A special case of matching is when the two structures being matched are both scene or model surfaces. The algorithm used for matching depends on the complexity the structures being matched. If the structures being matched are extended geometric entities such as planes or 3-D lines, then a discrete matching algorithm like the Interpretation Tree algorithm [31.79] can be used. It is suitable for matching small numbers (e.g., less than about 20–30) discrete objects, such as vertical edges seen in 2-D or 3-D. If there are M model and D data objects, then potentially there are M^D dif-

ferent matches. The key to efficient matching is to identify pairwise constraints that eliminate unsuitable matches. Constraints between pairs of model features and pairs of data features also greatly reduce the matching space. If the constraints eliminate enough features, a polynomial time algorithm results. The core of the algorithm is defined as follows. Let $\{m_i\}$ and $\{d_j\}$ be the sets of model and data features to be matched, $u(m_i, d_j)$ is true if m_i and d_j are compatible features, $b(m_i, m_j, d_k, d_l)$ is true if the four model and data features are compatible and T is the minimum number of matched features before a successful match is declared. Pairs is the set of successfully matched features. The function `true sizeof` counts the number of actual matches in the set, disregarding matches with the wildcard * which matches anything.

Algorithm 31.3

```

pairs=it(0,{})
if true sizeof(pairs) >= T, then success

function pairs=it(level,inpairs)
    if level >= T, then return inpairs
    if M-level+true sizeof(inpairs) < T
        then return {} % can never succeed
    for each d_i % loopD start
        if not u(m_level,d_i), then
            continue loopD
        for each (m_k,d_l) in inpairs
            if not b(m_level,m_k,d_i,d_l)
                then continue loopD
        endfor
        % have found a~successful new pair
        % to add
        pairs = it(level+1,
            union(inpairs, (m_level,d_i)))
        if true sizeof(pairs) >= T, then return
    endfor % loopD end

% no success, so try wildcard
it(level+1,union(inpairs, (m_level,*)))

```

31.3.5 Relative Pose Estimation

Central to many tasks is the estimation of the coordinate system relative position or pose transformation between two coordinate systems. For example, this might be the pose of a scanner mounted on a mobile vehicle relative to scene landmarks. Or, it might be the relative pose of some scene features as observed in two views taken from different positions.

We present here three algorithms that cover most instances of the pose estimation process, which differ slightly based on the type of feature being matched.

Point Set Relative Pose Estimation

The ICP algorithm can be used relative pose estimation as well (Sect. 31.3.1).

Straight Line Relative Pose Estimation

If 3-D lines are the features that are extracted, then the relative pose transformation can be estimated as follows. Assume N paired lines. The first set of lines is described by direction vectors $\{e_i\}$ and a point on each line $\{a_i\}$. The second set of lines is described by direction vectors $\{f_i\}$ and a point on each line $\{b_i\}$. In this algorithm, we assume that the direction vectors on the matched segments always point the same direction (i.e., are not inverted). This can be achieved by exploiting some scene constraints, or trying all combinations and eliminating inconsistent solutions. The points a_i and b_i need not correspond to the same point after alignment. The desired rotation matrix \mathbf{R} minimizes $\sum_i \|\mathbf{R}e_i - f_i\|^2$. Construct the $3 \times N$ matrices \mathbf{E} that consists of the vectors $\{e_i\}$ stacked up. Construct the $3 \times N$ matrices \mathbf{F} in a similar way from the vectors $\{f_i\}$. Compute the singular value decomposition $\text{svd}(\mathbf{F}\mathbf{E}') = \mathbf{U}'\mathbf{D}\mathbf{V}'$. Compute the rotation matrix $\mathbf{R} = \mathbf{V}\mathbf{U}'$. The translation estimate \mathbf{t} minimizes the sum of the square of the distances λ_i between the rotated points a_i and corresponding line (f_i, b_i) . Define matrix $\mathbf{L} = \sum_i (\mathbf{I} - f_i f_i') (\mathbf{I} - f_i')$. Define the vector $\mathbf{n} = \sum_i (\mathbf{I} - f_i f_i') (\mathbf{I} - f_i') (\mathbf{R}a_i - b_i)$. Then the translation is $\mathbf{t} = -\mathbf{L}^{-1}\mathbf{n}$.

Plane Relative Pose Estimation

Finally, if planes are the 3-D features extracted for matching, then the relative pose transformation can be estimated as follows. Assume N paired planes. The first set of planes is described by surface normals $\{e_i\}$ and a point on each plane $\{a_i\}$. The second set of planes is described by surface normals $\{f_i\}$ and a point on each plane $\{b_i\}$. Here we assume that the surface normals always point outward from the surface. The points a_i and b_i need not correspond to the same point after alignment. The desired rotation matrix \mathbf{R} minimizes $\sum_i \|\mathbf{R}e_i - f_i\|^2$. Construct the $3 \times N$ matrices \mathbf{E} that consists of the vectors $\{e_i\}$ stacked up. Construct the $3 \times N$ matrices \mathbf{F} in a similar way from the vectors $\{f_i\}$. Compute the singular value decomposition $\text{svd}(\mathbf{F}\mathbf{E}') = \mathbf{U}'\mathbf{D}\mathbf{V}'$ [31.45]. Compute the rotation matrix $\mathbf{R} = \mathbf{V}\mathbf{U}'$. The translation estimate \mathbf{t} minimizes the sum of the square of the distances λ_i between the rotated point a_i and the corresponding plane (f_i, b_i) . Define matrix $\mathbf{L} = \sum_i f_i f_i'$. Define the vector $\mathbf{n} = \sum_i f_i f_i' (\mathbf{R}a_i - b_i)$. Then the translation is $\mathbf{t} = -\mathbf{L}^{-1}\mathbf{n}$.

In all of the calculations described above, we assumed normally distributed errors. For techniques to robustify these sorts of calculations, see Zhang [31.80].

31.3.6 3-D Applications

This section links the techniques presented above to the robotics applications of 3-D localization of parts for robot manipulation, self-localization of robot vehicles and scene understanding for robot navigation. The robotics tasks mentioned here are discussed in more detail in other chapters in the series. While this chapter focusses on robotics applications, there are many other 3-D sensing applications. An area of much current research is that of acquiring 3-D models, particularly for reverse engineering of mechanical parts [31.81], historical artifacts [31.82], buildings [31.83] and people for computer games and movies (Cyberware Whole Body X 3-D Scanner).

The key tasks in robot manipulation are:

1. Identification of grasping points (Chaps. 37 and 38),
2. Identification of a collision free grasp (Chaps. 37 and 38),
3. Recognition of parts to be manipulated (Chap. 32) and
4. Position estimation of parts for manipulation (Chaps. 32 and 42).

The key tasks in robot navigation and self-localization are:

4. Identification of a navigable groundplane (Sect. 31.4),
5. Identification of a collision free path (Chap. 47),
6. Identification of landmarks (Chap. 45) and
7. Estimation of vehicle location (Chap. 53).

The mobile and assembly robotics tasks link together rather naturally. Tasks 1 and 5 have a connection, when we consider these tasks in the context of unknown parts or paths. Part grasping requires finding regions on a part that are graspable, which usually means locally planar patches that are large enough that a gripper can make good contact with them. Similarly, navigation usually requires smooth ground regions that are large enough for the vehicle – again locally planar patches. Both tasks are commonly based on triangulated scene methods to represent the data, from which connected regions of nearly coplanar patches can be extracted. The main difference between these two tasks is the groundplane detection task is looking for a larger patch, that must be on the *ground* and upward facing.

Tasks 2 and 6 require a method of representing empty space along the proposed trajectory of the gripper contacts or the vehicle. The voxel representation is good for this task.

Tasks 3 and 7 are model matching tasks and can use the methods of Sect. 31.3.3 to match observed scene features to prestored models of known parts or scene locations. Commonly used features are large planar surfaces, 3-D edges and 3-D feature points.

Tasks 4 and 8 are pose estimation tasks and can use the methods of Sect. 31.3.5 to estimate the pose of the object relative to the sensor or vehicle (i. e., sensor) relative to the scene. Again, commonly used features are large planar surfaces, 3-D edges and 3-D feature points.

31.4 Navigation and Terrain Classification and Mapping

One of the more compelling uses for range data is for navigation of mobile robot vehicles. Range data provides information about obstacles and free space for the vehicle, in a direct geometric form. Because of the real-time constraints of navigation, it is often impractical to reconstruct a full 3-D model of the terrain using the techniques presented in this chapter. Instead, most systems use an *elevation model*. An elevation model is a tessellated 2-D representation of space, where at each cell there is information about the distribution of 3-D points in the cell. In its simplest incarnation, the elevation map just contains the mean height of range points above the nominal ground plane (Fig. 31.20). This representation is sufficient for some indoor and urban environments; more sophisticated versions that determine a local plane, scatter of points in the cell, etc., are useful for more complicated off-road driving. Elevation maps marked with obstacles have obvious utility for planning a collision-free path for the vehicle.

31.4.1 Mobile Mapping

Laser range scanning provides an efficient way to actively acquire accurate and dense 3-D point clouds of object surfaces or environments. Mobile scanning is currently used for modeling in architecture and agriculture as well as urban and regional planning. Modern systems like the Riegl VMX-450 and the Lynx mobile mapper as produced by Optech work along the same basic principal. They combine a highly accurate global

positioning system (GPS), a high precision inertial measurement unit (IMU) and the odometry of the vehicle to compute the fully timestamped trajectory. Using a process called motion compensation this trajectory is then used to *unwind* the laser range measurements that were acquired by the 2-D laser scanner also mounted on the vehicle. The quality of the resulting point cloud depends on several factors:

- The calibration of the entire system, that is, the accuracy to which the position and orientation of each individual sensor in relation to the vehicle has been determined.
- The accuracy of the external positioning sensors, that is, the GPS, IMU and odometry.
- The availability of the GPS, as it may suffer temporary blackouts under bridges, in tunnels and between high-rises.
- The accuracy of the laser scanner itself.

The movement of the mobile laser scanner between time t_0 and t_n creates a trajectory $T = \{V_0, \dots, V_n\}$, where $V_i = (t_{x,i}, t_{y,i}, t_{z,i}, \theta_{x,i}, \theta_{y,i}, \theta_{z,i})$ is the 6-DOF (degree of freedom) pose of the vehicle at time t_i with $t_0 \leq t_i \leq t_n$. Using the trajectory of the vehicle a 3-D representation of the environment can be obtained by *unwinding* the laser measurements M to create the final map P . However, sensor errors in odometry, IMU and GPS as well as systematic calibration errors and the accumulation of pose errors during temporary GPS outages degrade the accuracy of the trajectory and therefore the point cloud quality. Furthermore, please note that modern systems easily create thousands of 3-D scan slices.

These mobile mapping systems extend the early work on 3-D reconstruction with two 2-D lasers under exploitation of the robot motion [31.84]. One laser scanner is scanning horizontal, one is mounted vertically. The resultant point cloud is typically registered using the pose of the robot as corrected by the 2-D SLAM algorithm, rather than any of the 3-D registration techniques covered in this chapter. The current state of the art developed by Bosse et al. [31.85] for improving overall map quality of mobile mappers in the robotics

Fig. 31.20 Elevation map in urban terrain. Each cell holds the height of the terrain at that point. More extensive features can also be incorporated: slope, point variance, etc.

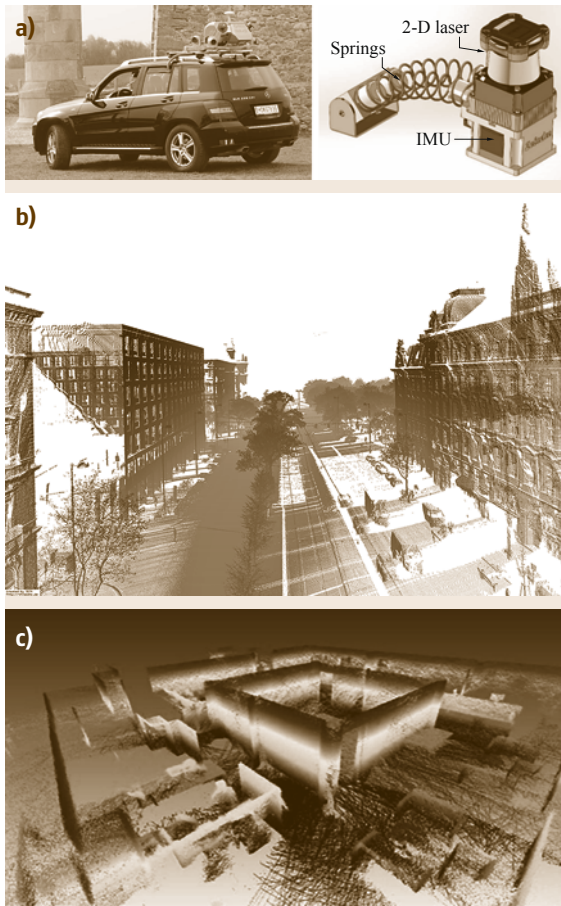

Fig. 31.21 (a) Mobile mapping car and (b) Zedbee handheld mapper. (c) 3-D point cloud acquired with the Riegl VMX-250 system. (d) 3-D point cloud from Zedbee

community is to coarsely discretize the time. This results in a partition of the trajectory into subscans that are treated rigidly. Then rigid registration algorithms like the ICP and other solutions to the SLAM problem are employed.

Figure 31.21 shows a car equipped with the Riegl VMX-450 mobile mapping system of the company Riegl laser measurement systems and the Zedbee handheld mapper from CSIRO. Figure 31.21 shows typical resulting 3-D point clouds as well.

31.4.2 Urban Navigation

In urban navigation, the environment is structured, with roads, buildings, sidewalks, and also moving objects – people and other vehicles. There are two main challenges: how to register laser scans from a fast-moving vehicle for consistent mapping, and how to detect moving objects using range scans (of course, other methods

Fig. 31.22 Elevation map of an urban scene, using 10×10 cm cells. Obstacles in red, ground plane in green (after [31.88])

are also used for detecting moving objects, for example, appearance-based vision).

Outdoor vehicles can use precision GPS, inertial measurement units, and wheel odometry to keep track of their position and orientation, typically with an extended Kalman filter. This method is good enough to obviate the need for precise registration matching among scans, as long as the motion model of the vehicle, and timing from the range scanner, is used to place each scan reading in its proper position in the world model. This method also works in relatively easy off-road terrain such as in the DARPA (Defense Advanced Research Projects Agency) Grand Challenge [31.86]. In all cases, the reduction of pose estimation error is critical for good performance [31.87].

Once scan readings are registered using the vehicle pose estimation, they can be put into an elevation map, and obstacles detected using the slope and vertical extent of the range readings in the cells of the map. A complication is that there may be multiple levels of elevation in an urban setting, for example, an overpass would not be an obstacle if it were high enough. One proposal is to use multiple elevation clusters within each cell; this technique is called a *multilevel surface map* (MLS, [31.88]). Each cell in the map stores a set of surfaces represented by a mean height and variance. Figure 31.22 shows an MLS with a cell size of 10 cm^2 , with ground plane and obstacles marked.

For dynamic objects, real-time stereo at 15–30 Hz can capture the motion of the objects. When the stereo rig is fixed, range background subtraction isolates just the moving objects [31.89]. When the rig is on a moving vehicle, the problem is more difficult, since the whole scene is moving with respect to the rig. It can be solved by estimating the motion of the rig with respect to the dominant rigid background of the scene. Let R, t be the motion of the rig between two frames, estimated by extracting features and matching them across the two

Fig. 31.23a–c Independent motion detection from a moving platform. Reference image on panel (a) is forward-projected using the motion homography to the image on panel (b); image on panel (c) is the difference with the actual image

temporal frames, using the techniques of Chap. 46. The homography $H(R, t)$ of (31.11) provides a direct projection of the disparity vectors $p_0 = [x_0, y_0, d_0, 1]$ of the first frame to their correspondences $H(R, t)p_0$ under R, t in the second frame. Using the homography allows the points in the reference frame to be directly projected onto the next frame, without translating to 3-D points. Figure 31.23 shows the projected pixels under rigid motion from a reference scene. The difference between the projected and actual pixels gives the independently moving objects (from [31.90]).

31.4.3 Rough Terrain

Rough outdoor terrain presents two challenges:

- There may be no extensive ground plane to characterize driveability and obstacles.
- Vegetation that is pliable and driveable may appear as an obstacle in range images.

Figure 31.24 shows a typical outdoor scene, with a small (1 m) robot driving through vegetation and rough ground [31.91]. Range data from stereo vision

Fig. 31.24 Rough terrain, no ground plane, driveable vegetation

on the robot will see the top of the vegetation and some ground points below. The elevation model can be extended to look at *point statistics* within each cell, to capture the notion of a local ground plane and penetrability related to vegetation. In [31.92], for example, the set of proposed features includes:

- Major plane slope using a robust fit (Sect. 31.3.2, *3-D Feature Representations and Extraction*)
- Height difference of max and min heights
- Points above the major plane
- Density: ratio of points in the cell to rays that pass through the cell.

The density feature is interesting (and expensive to compute), and attempts to characterize vegetation such as grass or bushes, by looking at whether range readings penetrate an elevation cell. The idea of using vegetation permeability to range readings has been discussed in several other projects on off-road driving [31.94–96].

Elevation map cells can be characterized as obstacles or driveable through learning or hand-built classifiers. Among the learning techniques are neural nets [31.92] and Gaussian mixture models with

Fig. 31.25 Classification using point statistics. Red is planar surface, blue is thin linear surface, green is scattered penetrable surface (after [31.93])

expectation-maximization learning [31.93]. The latter work also includes a lower level of interpretation, classifying surfaces into planar patches (ground plane, solid obstacles), linear features (telephone wires), and scattered features (vegetation). Figure 31.25 shows some results from a laser-scanned outdoor scene. Linear features such as telephone wires and the telephone pole are accurately determined, as well as vegetation with high penetrability.

Some additional problems occur in rough-terrain navigation. For planar laser rangefinders that are swept over the terrain by vehicle motion, the precision of vehicle pose estimation is important for accurate reconstruction. Attitude errors of less than 0.5° can cause false

positives in obstacle detection, especially for sweeps far ahead of the vehicle. In [31.87], this problem is solved by looking at the time of each laser reading, and noting a correlation between height errors and time difference in the readings.

Negative obstacles (ditches and cliffs) are difficult to detect with range information, because the sensor may not see the bottom of the obstacle. This is especially true for vehicle-mounted sensors that are not very high off the ground, and that are looking far ahead. Negative obstacles can be inferred when there is a gap in the ground plane, and a plane slanted upward at the back edge of the gap. Such artifacts can be efficiently found using column search on the disparity image [31.97].

31.5 Conclusions and Further Reading

Range sensing is an active and expanding field of research in robotics. The presence of new types of devices – flash ladars, multibeam ladars, on-camera stereo processing – and the continuing development of robust algorithms for object reconstruction, localization and mapping has helped to bring applications out of the laboratory and into the real world. Indoor navigation with ladars is already being exploited in commercial products (for example, [31.98]). As the basic capabilities become more robust, researchers are looking to perform useful tasks, such as fetching items or doing dishes [31.99].

Another set of challenges are found in less benign environments, such as urban and off-road driving (DARPA Grand Challenge and Urban Challenge [31.86]). Stereo vision and laser rangefinding also will play a role in helping to provide autonomy for a new generation of more-capable robotic platforms that rely on walking for locomotion [31.100]. The challenges are dealing with motion that is less smooth than wheeled platforms, environments that contain dynamic obstacles, and task-oriented recognition of objects.

32. 3-D Vision for Navigation and Grasping

Danica Kragic, Kostas Daniilidis

In this chapter, we describe algorithms for three-dimensional (3-D) vision that help robots accomplish navigation and grasping. To model cameras, we start with the basics of perspective projection and distortion due to lenses. This projection from a 3-D world to a two-dimensional (2-D) image can be inverted only by using information from the world or multiple 2-D views. If we know the 3-D model of an object or the location of 3-D landmarks, we can solve the pose estimation problem from one view. When two views are available, we can compute the 3-D motion and triangulate to reconstruct the world up to a scale factor. When multiple views are given either as sparse viewpoints or a continuous incoming video, then the robot path can be computer and point tracks can yield a sparse 3-D representation of the

world. In order to grasp objects, we can estimate 3-D pose of the end effector or 3-D coordinates of the graspable points on the object.

With the rapid progress and cost reduction in digital imaging, cameras became the standard and probably the cheapest sensor on a robot. Unlike positioning (global positioning system – GPS), inertial (IMU), and distance sensors (sonar, laser, infrared) cameras produce the highest bandwidth of data. Exploiting information useful for a robot from such a bit stream is less explicit than in case of GPS or a laser scanner but semantically richer. In the years since the first edition of the handbook, we had significant advances in hardware and algorithms. RGB-D sensors like the Primesense Kinect enabled a new generation of full model reconstruction systems [32.1] with an arbitrary camera motion. Google’s project Tango [32.2] established the state of the art in visual odometry using the latest fusion methods between visual and inertial data ([32.3] and VIDEO 120). 3-D modeling became a commodity software (see, for example, 123D Catch App from

Autodesk) and the widely used open source Bundler ([32.4] VIDEO 121) has been possible by advances in wide baseline matching and bundle adjustment. Methods for wide baseline matching have been proposed for several variations of pose and structure from motion [32.5]. Last, the problem of local minima for non-minimal overconstrained solvers has been addressed by a group of method using Branch and Bound global optimization of a sum of fractions subject to convex constraints [32.6] or an L_∞ -norm of the error function [32.7].

Let us consider the two main robot perception domains: navigation and grasping. Assume for example the scenario that a robot vehicle is given the task of going from place A to place B given as instruction only intermediate visual landmarks and/or GPS waypoints. The robot starts at A and has to decide where is a drivable path. Such a decision can be accomplished through

the detection of obstacles from at least two images by estimating a depth or occupancy map with a *stereo* algorithm. While driving, the robot wants to estimate its trajectory which can be accomplished with a *matching* and *structure from motion* algorithm. The result of the trajectory can be used to build a lay out of the environment through *dens matching* and *triangulation* which in turn can be used as a reference for a subsequent *pose estimation*. At each time instance the robot has to parse the surrounding environment for risks like pedestrians, or for objects it is searching for like a trash-can. It has to become aware of *loop closing* or a reentry if the robot has been kidnaped or blind for a while. This can be accomplished through *object and scene recogni-*

tion yielding the *what* and *where* of objects around the robot. In an extreme scenario, a vehicle can be left to explore a city and build a semantic 3-D map as well as a trajectory of all places it visited, the ultimate *visual simultaneous localization and semantic mapping* problem. In the case of grasping, the robot detects an object given a learnt representation, and subsequently, it has to estimate the *pose* of the object and in some cases its shape by *triangulation*. When a camera is not mounted on an end-effector, the *absolute orientation* between the hand the object has to be found.

In the next section we will present the geometric foundations for 3-D vision and in the last section we describe approaches for grasping.

32.1 Geometric Vision

Let us start by introducing the projection of the world to an image plane. Assume that a point in the world (X, Y, Z) has coordinates (X_{ci}, Y_{ci}, Z_{ci}) with respect to the coordinate system of a camera c_i related to each other by the following transformation

$$\begin{pmatrix} X_{ci} \\ Y_{ci} \\ Z_{ci} \end{pmatrix} = \mathbf{R}_i \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} + \mathbf{T}_i, \quad (32.1)$$

where \mathbf{R}_i is a rotation matrix whose columns are the world axes with respect to the camera. The translation vector \mathbf{T}_i is starting from the origin of the camera and ending at the origin of the world coordinate system. The rotation matrix is orthogonal $\mathbf{R}^T \mathbf{R} = \mathbf{1}$ with determinant one. We assume that the center of projection is the origin of the coordinate system and that the optical axis is the Z_{ci} axis of the camera. If we assume that the image plane is the plane $Z_{ci} = 1$ then the image coordinates (x_i, y_i) read

$$x_i = \frac{X_{ci}}{Z_{ci}}, \quad y_i = \frac{Y_{ci}}{Z_{ci}}. \quad (32.2)$$

In practice, what we measure are the pixel coordinates (u_i, v_i) in the image which are related to image coordinates (x_i, y_i) with the affine transformation

$$u_i = f\alpha x_i + \beta y_i + c_u, \quad v_i = fy_i + c_v, \quad (32.3)$$

where f is the distance of the image plane to the projection center measured in pixels. It is also called focal length, because they are considered approximately equal. The aspect ratio α is a scaling induced by nonsquare sensor cells or different sampling rates horizontally and vertically. The skew factor β accounts

for a shearing induced by a nonperfectly frontal image plane. The image center c_u, c_v is the point of intersection of the image plane with the optical axis called the image center. These five parameters are called intrinsic parameters and the process of recovering them is called intrinsic calibration. Upon recovering them we can talk about a calibrated system and we can work with the image coordinates (x_i, y_i) instead of the pixel coordinates (u_i, v_i) . In many vision systems in particular on mobile robots, wide-angle lenses introduce a radial distortion around the image center which can be modelled polynomially

$$x_i^{\text{dist}} = x_i(1 + k_1 r + k_2 r^2 + k_3 r^3 + \dots)$$

$$y_i^{\text{dist}} = y_i(1 + k_1 r + k_2 r^2 + k_3 r^3 + \dots)$$

$$\text{where } r^2 = x_i^2 + y_i^2,$$

where we temporarily assumed that the image center is at $(0,0)$. The image coordinates (x_i, y_i) in ((32.3)) have to be replaced with the distorted coordinates $(x_i^{\text{dist}}, y_i^{\text{dist}})$.

32.1.1 Calibration

Recovering the intrinsic parameters when we can make multiple views of a reference pattern like a checker board without variation of the intrinsic parameters has become a standard procedure using tools like the MATLAB calibration toolbox or Zhang's OpenCV calibration function [32.8]. When intrinsics like the focal length vary during operation and viewing reference patterns is not practically feasible, we rely on the state of the art method by Pollefeys et al. [32.9, 10]. When all intrinsic are unknown on the Kruppa equations and

several stratified self-calibration approaches [32.11, 12] which require at least three views. Apart radial distortion, the projection relations shown above can be summarized in matrix form. By denoting

$$\mathbf{u}_i = (u_i, v_i, 1)$$

and

$$\mathbf{X} = (X, Y, Z, 1)$$

we obtain

$$\lambda_i \mathbf{u}_i = \mathbf{K}_i (\mathbf{R}_i \quad \mathbf{T}_i) \mathbf{X} = \mathbf{P} \mathbf{X}, \quad (32.4)$$

where $\lambda_i = Z_{ci}$ is the depth of point \mathbf{X} in camera coordinates and \mathbf{P} is the 3×4 projection matrix. The depth λ_i which can be eliminated to obtain two equations relating the world to the pixel coordinates.

32.1.2 Pose Estimation or PnP

When we have landmarks in the world with known positions \mathbf{X} and we can measure their projections, the problem of recovering the unknown rotation and translation in the calibrated case is called pose estimation or the Perspective-n-Point problem (PnP). Of course, it presumes the identification of the world points in the image. In robotics, the pose estimation is a variant of the localization problem in a known environment. When grasping objects of known shape PnP yields the target pose for an end-effector module the grasping point positions. We assume that a camera is calibrated and that measurements of N points are given in world coordinates $\mathbf{X}_{j=1..N}$ and calibrated image coordinates $\mathbf{x}_{j=1..N}$. Let us assume two scene points and denote the known angle between their projections \mathbf{x}_1 and \mathbf{x}_2 as δ_{12} (Fig. 32.1). Let us denote the squared distance $\|\mathbf{X}_i - \mathbf{X}_j\|^2$ with d_{ij}^2 and the lengths of \mathbf{X}_j with d_j^2 . Then cosine law reads

$$d_i^2 + d_j^2 - 2d_i d_j \cos \delta_{ij} = d_{ij}^2. \quad (32.5)$$

If we can recover d_i and d_j the rest will be an absolute orientation problem

$$d_j \mathbf{x}_j = \mathbf{R} \mathbf{X}_j + \mathbf{T} \quad (32.6)$$

to recover translation and rotation between camera and world coordinate system.

Minimal Solution

The cosine law has two unknowns d_1 and d_2 so with three points we should be able to solve for the pose estimation problem. Indeed, three points yield a system of

three quadratic equations in three unknowns, so it will have a maximum of eight solutions.

We follow here the analysis of the classic solution in [32.13] and set $d_2 = u d_1$ and $d_3 = v d_1$ and solve all three equations for d_1

$$d_1^2 = \frac{d_{23}^2}{u^2 + v^2 - 2uv \cos \delta_{23}},$$

$$d_1^2 = \frac{d_{13}^2}{1 + v^2 - 2v \cos \delta_{13}},$$

$$d_1^2 = \frac{d_{12}^2}{u^2 + 1 - 2u \cos \delta_{12}},$$

which is equivalent to two quadratic equations in u and v

$$\begin{aligned} d_{12}^2(1 + v^2 - 2v \cos \delta_{13}) \\ = d_{13}^2(u^2 + 1 - 2u \cos \delta_{12}), \end{aligned} \quad (32.7)$$

$$\begin{aligned} d_{13}^2(u^2 + v^2 - 2uv \cos \delta_{23}) \\ = d_{23}^2(1 + v^2 - 2v \cos \delta_{13}). \end{aligned} \quad (32.8)$$

Solving (32.8) for u^2 and substituting in (32.7) allows solving E1 for u because u appears linearly. Substituting u back in (32.8) yields a quartic in v which can have as many as four real roots. For each v we obtain two roots for u through any of the quadratic equations yielding a maximum of eight solutions [32.13, 14]. Popular pose estimation algorithms are based either on an iterative method [32.15, 16] or linear versions using auxiliary unknowns of higher dimension [32.17, 18].

A more recent method [32.19] for n world points expresses 3-D points as the barycentric coordinates with

Fig. 32.1 Pose estimation problem: A camera seeing 3 points at unknown distances d_1 , d_2 , and d_3 with known angles between the rays and known point distances d_{12} , d_{13} , d_{23}

respect to four virtual control points

$$\mathbf{X}_i = \sum_{j=1}^4 \alpha_{ij} \mathbf{C}_j, \quad \text{where} \quad \sum_{j=1}^4 \alpha_{ij} = 1.$$

A rigid transformation to the camera coordinate system leaves the barycentric coordinates invariant and a perspective projection yields

$$\lambda_i \mathbf{x}_i = \sum_{j=1}^4 \alpha_{ij} (X_{ci}, Y_{ci}, Z_{ci})^T.$$

Eliminating λ_i yields two linear equations for each point

$$\begin{aligned} \sum_{j=1}^4 \alpha_{ij} C_{x_{cj}} &= \alpha_{ij} x_i C_{z_{cj}} \\ \sum_{j=1}^4 \alpha_{ij} C_{y_{cj}} &= \alpha_{ij} y_i C_{z_{cj}} \end{aligned}$$

with the coordinate triples of the control points in the camera frame being the 12 unknowns. This is a linear homogeneous system with the solution being the nullspace of a $2n \times 12$ matrix. The unknown control points are found up to a scale factor which is easily fixed because we know the inter point distances. The pose is found from absolute orientation between control points in the camera and the world frame. This yields a very efficient solution for $n \geq 6$ points but leaves you with the initial choice of the control points as a factor affecting the solution.

In case that $n \geq 4$ points lie on a plane we can compute the homography H between the world and the camera plane [32.8]. Assuming $Z = 0$ is the world plane the homography reads

$$\begin{pmatrix} u \\ v \\ w \end{pmatrix} \approx K \underbrace{\begin{pmatrix} r_1 & r_2 & T \end{pmatrix}}_H \begin{pmatrix} X \\ Y \\ W \end{pmatrix},$$

where $r_{1,2}$ are the first two columns of the rotation matrix and \approx denotes the projective equivalence, namely, for any two points \mathbf{p} and \mathbf{p}' in the projective plane $\mathbf{p} \approx \mathbf{p}'$ iff $\mathbf{p} = \lambda \mathbf{p}'$ for real $\lambda \neq 0$. Hence the first two columns of $K^{-1}H$

$$K^{-1}H = \begin{pmatrix} h'_1 & h'_2 & h'_3 \end{pmatrix}$$

have to be orthogonal. We seek thus an orthogonal matrix \mathbf{R} that is the closest to $\begin{pmatrix} h'_1 & h'_2 & h'_1 \times h'_2 \end{pmatrix}$

$$\arg \min_{\mathbf{R} \in \text{SO}(3)} \|\mathbf{R} - \begin{pmatrix} h'_1 & h'_2 & h'_1 \times h'_2 \end{pmatrix}\|_F^2.$$

If the singular value decomposition (SVD) of

$$\begin{pmatrix} h'_1 & h'_2 & h'_1 \times h'_2 \end{pmatrix} = USV^T,$$

then the solution is [32.20]

$$\mathbf{R} = U \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \det(UV^T) \end{pmatrix} V^T. \quad (32.9)$$

The diagonal matrix is a projection from the orthogonal group $O(3)$ to the special orthogonal group $SO(3)$.

Last, we present a method [32.21] for n points that computes all local minima of the over constrained PnP problem. This involves solving the first derivatives explicitly with respect to the pose unknowns. To achieve this, following observation allows the elimination of the depths λ and the translation. Rigid transformation $\lambda \mathbf{x} = \mathbf{R}\mathbf{X} + \mathbf{T}$ can be written for n points as a linear system for $\lambda_{j=1..n}$ and the translation \mathbf{T}

$$\begin{pmatrix} \mathbf{x}_1 & & & -I \\ & \ddots & & \vdots \\ & & \mathbf{x}_n & -I \end{pmatrix} \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_n \\ \mathbf{T} \end{pmatrix} = \begin{pmatrix} \mathbf{R}\mathbf{X}_1 \\ \vdots \\ \mathbf{R}\mathbf{X}_n \end{pmatrix}.$$

We can solve for the unknown depths-translation vector and back substitute it into a least squares minimization problem with respect to rotation parameters. It turns out that if we use the three Rodriguez parameters as rotation parametrization the necessary conditions for an extremum (vanishing derivatives) turn out to be three cubic equations [32.21]. Last we would like to point out to the reader that a nonlinear function of the rotation matrix can also be solved as an optimization problem on the Lie-group $SO(3)$ [32.22–24] for the case of line correspondences.

32.1.3 Triangulation

When we know both the intrinsics and extrinsics or their summarization in matrix \mathbf{P} and we measure a point we cannot recover its depth from just one camera position. Assuming that we have the projection of the same point \mathbf{X} in two cameras

$$\begin{aligned} \lambda_1 \mathbf{u}_1 &= \mathbf{P}_1 \begin{pmatrix} \mathbf{X} \\ 1 \end{pmatrix}, \\ \lambda_2 \mathbf{u}_2 &= \mathbf{P}_2 \begin{pmatrix} \mathbf{X} \\ 1 \end{pmatrix}, \end{aligned} \quad (32.10)$$

with known projection matrices \mathbf{P}_1 and \mathbf{P}_2 we can recover the position \mathbf{X} in space, a process well known

as triangulation. Observe that we can achieve triangulation without decomposing the projection matrices into intrinsic and extrinsic parameters, we need though to remove the distortion in order to write them as above.

Having correspondences of the same point in two cameras with known projection matrices \mathbf{P}_l and \mathbf{P}_r we can solve the two projection equations for the world point \mathbf{X} . It is worth noting that each point provides two independent equations so that triangulation becomes an overconstrained problem for two views. This is not a contradiction since two rays do not intersect in general in space unless they satisfy the epipolar constraint as presented in the next paragraph. The following matrix in the left hand side has in general rank 4 unless the epipolar constraint is satisfied in which case it has rank 3.

$$\begin{pmatrix} x\mathbf{P}_l(3, :) - \mathbf{P}_l(1, :) \\ y\mathbf{P}_l(3, :) - \mathbf{P}_l(2, :) \\ x\mathbf{P}_r(3, :) - \mathbf{P}_r(1, :) \\ y\mathbf{P}_r(3, :) - \mathbf{P}_r(2, :) \end{pmatrix} \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix} = \mathbf{0}, \quad (32.11)$$

where $\mathbf{P}(i, :)$ means the i -th row of matrix \mathbf{P} .

Obviously, the homogeneous system above can be transformed into an inhomogeneous linear system with unknowns (X, Y, Z) . Otherwise it can be solved by finding the vector closest to the null-space of the 4×4 matrix above using **SVD**. A thorough treatment of triangulation is the classic [32.25].

32.1.4 Moving Stereo

Imagine now that a rigid stereo system consisting of cameras c_l (left) and c_r (right)

$$\mathbf{u}_{li} \approx \mathbf{P}_l \mathbf{X}_i, \quad (32.12)$$

$$\mathbf{u}_{ri} \approx \mathbf{P}_r \mathbf{X}_i, \quad (32.13)$$

is attached to a moving robot and observe this system at two time instances

$$\mathbf{X}_0 = \mathbf{R}_1 \mathbf{X}_1 + \mathbf{T}_1, \quad (32.14)$$

where \mathbf{X}_0 are point coordinates with respect to the world coordinate system, usually assumed aligned with one of the camera instances, and \mathbf{X}_1 are the coordinates of the same point with respect to the camera rig, after a motion $(\mathbf{R}_1, \mathbf{T}_1)$. To estimate the motion of the rig, we have to solve two correspondence problems, first, between left and right image, and second, between left (or right) at the first time instance and left (or right, respectively) at the second time instance. The left to right correspondence enable the solution of the triangulation problem at each time instance. Motion can be obtained

then by solving equations (32.14) for $(\mathbf{R}_1, \mathbf{T}_1)$, a problem called absolute orientation. Alternatively one can avoid the second triangulation and solve the pose estimation problem between triangulated points in 3-D and points in the left image only. The most popular visual odometry system today is **libviso** [32.26] and is based on a moving stereo rig ( VIDEO 122).

Absolute Orientation

The treatment for moving stereo will be short and the reader is referred to a similar treatment in the chapter about range sensing. We assume that correspondences between two time instances have been established based on tracking in the images so that we can formulate equations of the form

$$\mathbf{X}_2 = \mathbf{R} \mathbf{X}_1 + \mathbf{T}.$$

The standard way [32.20, 27] to solve this problem is to eliminate the translation by subtracting the centroids yielding

$$\mathbf{X}_2 - \bar{\mathbf{X}}_2 = \mathbf{R}(\mathbf{X}_1 - \bar{\mathbf{X}}_1).$$

We need at least three points in total to obtain at least two noncollinear mean-free $\mathbf{X} - \bar{\mathbf{X}}$ vectors. If we concatenate the mean free vectors for n points into an $n \times 3$ matrix $A_{1,2}$ we can formulate the following minimization of the Frobenius norm

$$\min_{\mathbf{R} \in \text{SO}(3)} \|\mathbf{A}_2 - \mathbf{R} \mathbf{A}_1\|_F,$$

which is known as the Procrustes problem. It can be shown [32.20] that the solution is obtained through **SVD** as in (32.9) where U, V are obtained from the singular value decomposition

$$\mathbf{A}_2 \mathbf{A}_1^T = \mathbf{U} \mathbf{S} \mathbf{V}^T.$$

Solutions are usually obtained with RANSAC by sampling triples of points and verification with the Procrustes method.

32.1.5 Structure from Motion

Relax now the assumption that projection matrices are known and remain with measuring and matching corresponding points \mathbf{u}_1 and \mathbf{u}_2 . This is the well known structure from motion problem or more precisely structure and 3-D-motion from 2-D motion. In photogrammetry, it is well known as relative orientation problem. Even after eliminating the λ 's from equations (32.12)

or by writing them in projective equivalence form

$$\begin{aligned} u_1 &\approx \mathbf{P}_1 \begin{pmatrix} X \\ 1 \end{pmatrix}, \\ u_2 &\approx \mathbf{P}_2 \begin{pmatrix} X \\ 1 \end{pmatrix}, \end{aligned} \quad (32.15)$$

we realize that if $(X, \mathbf{P}_1, \mathbf{P}_2)$ is a solution then $(\mathbf{H}X, \mathbf{P}_1\mathbf{H}^{-1}, \mathbf{P}_2\mathbf{H}^{-1})$ is a solution, too, where \mathbf{H} is an invertible 4×4 real matrix or in other words a collineation in \mathbb{P}^3 . Even if we align the world coordinate system with the coordinate system of the first camera, which practice is common

$$\begin{aligned} u_1 &\approx (\mathbf{I} \ 0) X, \\ u_2 &\approx \mathbf{P}_2 X, \end{aligned} \quad (32.16)$$

we remain with the same ambiguity where \mathbf{H} is of the form

$$\mathbf{H} \approx \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ h_{41} & h_{42} & h_{43} & h_{44} \end{pmatrix}, \quad (32.17)$$

with $h_{44} \neq 0$. This ambiguity is possible when the projection matrices are arbitrary rank 3 real matrices without any constraint on their elements. If we assume that we have calibrated our cameras then the projection matrices depend only on displacements

$$\begin{aligned} u_1 &\approx (\mathbf{I} \ 0) X, \\ u_2 &\approx (\mathbf{R} \ T) X, \end{aligned} \quad (32.18)$$

and the only remaining ambiguity is the scale ambiguity where \mathbf{H} looks like an identity matrix except $h_{44} = s \neq 1$ being the scale factor. In other words if (\mathbf{R}, T, X) is a solution then $(\mathbf{R}, sT, 1/sX)$ is a solution, too. These remarks generalize in multiple views. Because, in robotics the (\mathbf{R}, T) matrices correspond to location and X to mapping of the environment, the problem has the more proper term **SLAM**: Simultaneous localization and mapping. However, because the term **SLAM** has been used with a variety of sensors like sonar and laser range scanners, the term monocular **SLAM** is better suited to describe structure from motion from multiple views [32.28].

Epipolar Geometry

This is probably one of the most studied problems in computer vision. We constrain ourselves to the calibrated case which is most relevant to robotics applications. The necessary and sufficient condition for the

intersection of the two rays $\mathbf{R}\mathbf{x}_1$ and \mathbf{x}_2 is that the two rays are coplanar with the baseline T

$$\mathbf{x}_2^T (T \times \mathbf{R}\mathbf{x}_1) = 0, \quad (32.19)$$

which is the epipolar constraint (Fig. 32.2). To avoid the scale ambiguity we assume that T is a unit vector. We proceed by summarizing the unknowns into one matrix

$$\mathbf{E} = \hat{T}\mathbf{R} \quad (32.20)$$

where \hat{T} is the 3×3 skew-symmetric matrix to the vector T . The \mathbf{E} matrix is called the essential matrix. The epipolar constraint reads then

$$\mathbf{x}_2^T \mathbf{E} \mathbf{x}_1 = 0, \quad (32.21)$$

which is the equation of a line in the \mathbf{x}_2 plane with coefficients $\mathbf{E}\mathbf{x}_1$ or a coefficient of a line in the \mathbf{x}_1 plane with coefficients $\mathbf{E}^T\mathbf{x}_2$. These lines are called epipolar and form pencils whose centers are the epipoles \mathbf{e}_1 and \mathbf{e}_2 , in the first and second image plane respectively. The epipoles are the intersections of the baseline with the two image planes, hence $\mathbf{e}_2 \approx T$ and $\mathbf{e}_1 \approx -\mathbf{R}^T T$. Looking at the equations of the epipolar lines we can immediately infer that $\mathbf{E}^T \mathbf{e}_1 = 0$ and $\mathbf{E} \mathbf{e}_2 = 0$.

The set of all essential matrices

$$\begin{aligned} \mathcal{E} &= \{ \mathbf{E} \in \mathbb{R}^{3 \times 3} \mid \mathbf{E} = \hat{T}\mathbf{R}, \\ &\text{where } T \in \mathbb{S}^2 \text{ and } \mathbf{R} \in \text{SO}(3) \} \end{aligned}$$

has been characterized as a manifold of dimension 5 [32.29]. It has been proven [32.30] that

Proposition 32.1

A matrix $\mathbf{E} \in \mathbb{R}^{3 \times 3}$ is essential if and only if it has two singular values equal to each other and third singular value equal zero.

Fig. 32.2 A point is perspective projected to calibrated image vectors $\mathbf{R}\mathbf{x}_1$ and \mathbf{x}_2 which are coplanar with baseline T

We present here Nister's method [32.31] for recovering an essential matrix from five point correspondences and which gained in popularity because of its suitability for RANSAC methods.

Minimal Case

We expand the epipolar constraint in terms of homogeneous coordinates $\mathbf{x}_1 = (x_1, y_1, z_1)$ and $\mathbf{x}_2 = (x_2, y_2, z_2)$ (when the points are not at infinity $z_i = 1$) and obtain

$$\begin{pmatrix} x_1 \mathbf{x}_2^T & y_1 \mathbf{x}_2^T & z_1 \mathbf{x}_2^T \end{pmatrix} E_s = 0, \quad (32.22)$$

where E_s is the row by row stacked version of matrix \mathbf{E} . When we use only five point correspondences the resulting linear homogeneous system will have as a solution any vector in the four dimensional kernel of the data matrix

$$E_s = \lambda_1 \mathbf{u}_1 + \lambda_2 \mathbf{u}_2 + \lambda_3 \mathbf{u}_3 + \lambda_4 \mathbf{u}_4. \quad (32.23)$$

At this point we want the matrix \mathbf{E} resulting from E_s to be an essential matrix satisfying Proposition 32.1. It has been proven [32.30] that

Proposition 32.2

A matrix $\mathbf{E} \in \mathbb{R}^{3 \times 3}$ is essential if and only if

$$\mathbf{E} \mathbf{E}^T \mathbf{E} = \frac{1}{2} \text{trace}(\mathbf{E} \mathbf{E}^T) \mathbf{E}. \quad (32.24)$$

Though the $\det(\mathbf{E}) = 0$ constraint can be inferred from (32.24) we are still going to use it together with (32.24) to obtain ten cubic equations in the elements of \mathbf{E} . As described in [32.31], one can obtain a tenth degree polynomial in λ_4 . The number of real roots of this polynomial are computed with a Sturm sequence. There is no proof beyond physical plausibility of the existence of at least one solution that a real root will exist at all. Several alternative 5-point solvers have been proposed since Nister's paper [32.32–35] and an extensive list including code has been established by Pajdla's group [32.36].

Assuming that we have recovered an essential matrix from point correspondences, the next task is to recover an orthogonal matrix \mathbf{R} and a unit vector translation \mathbf{T} from the essential matrix. If $E = U \text{diag}(\sigma, \sigma, 0) V^T$, there are four solutions for the pair $(\hat{\mathbf{T}}, \mathbf{R})$

$$\begin{aligned} (\hat{\mathbf{T}}_1, \mathbf{R}_1) &= (U \mathbf{R}_{z,+\pi/2} \Sigma U^T, U \mathbf{R}_{z,+\pi/2}^T V^T), \\ (\hat{\mathbf{T}}_2, \mathbf{R}_2) &= (U \mathbf{R}_{z,-\pi/2} \Sigma U^T, U \mathbf{R}_{z,-\pi/2}^T V^T), \\ (\hat{\mathbf{T}}_1, \mathbf{R}_2) &= (U \mathbf{R}_{z,+\pi/2} \Sigma U^T, U \mathbf{R}_{z,-\pi/2}^T V^T), \\ (\hat{\mathbf{T}}_2, \mathbf{R}_1) &= (U \mathbf{R}_{z,-\pi/2} \Sigma U^T, U \mathbf{R}_{z,+\pi/2}^T V^T), \end{aligned}$$

where R_z denotes rotation around the z -axis. The four solutions can be split into two two-fold ambiguities:

- *Mirror ambiguity*: If T is a solution, then $-T$ is a solution, too. There is no way to disambiguate from the epipolar constraint: $\mathbf{x}_2^T ((-T) \times \mathbf{R} \mathbf{x}_1) = 0$.
- *Twisted pair ambiguity*: If R is a solution, then also $R_{T,\pi} R$ is a solution. The first image is *twisted* around the baseline 180 degrees.

These ambiguities are resolved by checking if depths of triangulated points are positive.

Critical Ambiguities

The approach with five point correspondences has a finite number of feasible (feasible means that they may produce multiple interpretations of structures in front of the camera) solutions when the points in the scene lie on a plane (a two fold ambiguity) [32.37] or when the points on the scene and the camera centers lie on a double sheet hyperboloid with the additional constraint that the camera centers lie symmetrically to the main generator of the hyperboloid [32.38]. These are inherent ambiguities which hold for any number of point correspondences when one seeks a solution for an exact essential matrix.

When someone is solving the linear least squares system for the essential matrix, a planar scene as well as the case of all points and the camera centers lying on a quadric causes a rank deficiency of the system and thus infinite solutions for \mathbf{E} .

Beyond the ambiguous situations, there is a considerable amount of literature regarding instabilities in the two view problem. In particular, it has been shown [32.37, 39, 40] that a small field of view and insufficient depth variation can cause an indeterminacy in the estimation of the angle between translation and optical axis. An additional small rotation can cause a confounding between translation and rotation [32.41]. Moreover, it has been shown, that there exist local minima close to the global minimum that can fool any iterative scheme [32.42, 43].

3-Point SfM

Minimal solutions based on 5 points are still too slow to be used on mobile platforms where additional information like a reference gravity vector might be obtained from an IMU. We present here a recent solution using a reference direction and only 3 points [32.44].

We are given three image correspondences from calibrated cameras, and a single directional correspondence like the gravity vector or a vanishing point. This problem is equivalent to finding the translation vector \mathbf{t} and a rotation angle θ around an arbitrary rotation axis.

Let us choose the arbitrary rotation axis to be $\mathbf{e}_2 = [0, 1, 0]^T$. After taking the directional constraint into account, from the initial five parameters in the essential matrix, we now only have to estimate three. We can use the axis-angle parameterization of a rotation matrix to rewrite the essential matrix constraint as follows

$$\mathbf{p}_{2i}^T \tilde{E} \mathbf{p}_1 = 0, \quad (32.25)$$

where

$$\tilde{E} = \hat{\mathbf{t}}(I + \sin \theta \hat{\mathbf{e}}_2 + (1 - \cos \theta) \hat{\mathbf{e}}_2^2),$$

and $\hat{\mathbf{t}} = (x, y, 1)$.

Each image point correspondence gives us one such equation, for a total of three equations in three unknowns (elements of \mathbf{t} and θ). To create a polynomial system, we set $s = \sin \theta$ and $c = \cos \theta$, and add the trigonometric constraint $s^2 + c^2 - 1 = 0$, for a total of four equations in four unknowns. In order to reduce the number of unknowns, we choose the direction of the epipole by assuming that the translation vector $\hat{\mathbf{t}}$ has the form $[x, y, 1]^T$. This means that for each $\hat{\mathbf{t}}$ that we recover, $-\hat{\mathbf{t}}$ will also need to be considered as a possible solution.

Once we substitute for \tilde{E} in (32.25), the resulting system of polynomial equations has the following form

$$\begin{aligned} a_{i1}xs + a_{i2}xc + a_{i3}ys + a_{i4}yc \\ + a_{i5}x - a_{i2}s + a_{i1}c + a_{i6} = 0 \end{aligned} \quad (32.26)$$

for $i = 1, \dots, 3$, and the equation

$$s^2 + c^2 - 1 = 0. \quad (32.27)$$

This polynomial system can be solved in closed form and has up to four solutions. The total number of possible pose matrices arising from our formulation is therefore at most 8, when we take into account the fact that we have to consider the sign ambiguity in translation.

32.1.6 Multiple Views SfM

When we talk about simultaneous localization and mapping we obviously mean over a longer period of time. The question is how do we integrate additional frames in our 3-D motion estimation (localization) process.

To exploit multiple frames we introduce rank constraints [32.45]. We assume that the world coordinate system coincides with the coordinate system of the first frame and that a scene point is projected to \mathbf{x}_i in the i -th

frame and that its depth with respect to the 1st frame is λ_1

$$\lambda_i \mathbf{x}_i = \mathbf{R}_i(\lambda_1 \mathbf{x}_1) + \mathbf{T}_i. \quad (32.28)$$

Taking the cross product with \mathbf{x}_i and writing it for n frames yields a homogeneous system

$$\begin{pmatrix} \hat{\mathbf{x}}_2 \mathbf{R}_2 \mathbf{x}_1 & \hat{\mathbf{x}}_2 \mathbf{T}_2 \\ \vdots & \vdots \\ \hat{\mathbf{x}}_n \mathbf{R}_n \mathbf{x}_1 & \hat{\mathbf{x}}_n \mathbf{T}_n \end{pmatrix} \begin{pmatrix} \lambda_1 \\ 1 \end{pmatrix} = 0, \quad (32.29)$$

that has the depth of a point in the first frame as an unknown. The $3n \times 2$ multiple view matrix has to have rank one [32.46], a constraint that infers both the epipolar and the trifocal equations. The least squares solution for the depth can easily be derived as

$$\lambda_1 = - \frac{\sum_{i=1}^n (\mathbf{x}_i \times \mathbf{T}_i)^T (\mathbf{x}_i \times \mathbf{R}_i \mathbf{x}_1)}{\|\mathbf{x}_i \times \mathbf{R}_i \mathbf{x}_1\|^2}. \quad (32.30)$$

Given a depth for each point we can solve for motion by rearranging the multiple views constraint (32.29) as

$$\begin{pmatrix} \lambda_1^1 \mathbf{x}_1^{1T} \otimes \hat{\mathbf{x}}_1^1 & \hat{\mathbf{x}}_1^1 \\ \vdots & \vdots \\ \lambda_1^n \mathbf{x}_1^{nT} \otimes \hat{\mathbf{x}}_1^n & \hat{\mathbf{x}}_1^n \end{pmatrix} \begin{pmatrix} \mathbf{R}_i^{\text{stacked}} \\ \mathbf{T}_i \end{pmatrix} = 0, \quad (32.31)$$

where \mathbf{x}_i^n is the n -th image point in the i -th frame and $\mathbf{R}_i, \mathbf{T}_i$ is the motion from 1st to the i -th frame and $\mathbf{R}_i^{\text{stacked}}$ is the 12×1 vector of stacked elements of the rotation matrix \mathbf{R}_i . Suppose that \mathbf{k} is the 12×1 kernel (or closest kernel in a least squares sense) of the $3n \times 12$ matrix in the left hand side obtained through singular value decomposition and let us call \mathbf{A} the 3×3 matrix obtained from the first 9 elements of \mathbf{k} and \mathbf{a} the vector of elements 10–12. To obtain a rotation matrix we follow the SVD steps in the solution of absolute orientation (32.14) to find the closest orthogonal matrix to an arbitrary invertible matrix.

Bundle Adjustment

On top of such an approach, a bundle adjustment [32.47] minimizes the sum of all deviations between image coordinates and the backprojections of the points to be reconstructed.

$$\arg \min_{\mathbf{R}^f, \mathbf{T}^f, \mathbf{x}_p} \epsilon^T \mathbf{C}^{-1} \epsilon,$$

minimized with respect to all $6(F-1)$ motions and $3N-1$ structure unknowns, where ϵ is the vector con-

taining all errors

$$\epsilon_p^f = \begin{pmatrix} x_p^f - \frac{R_{11}^f X_p + R_{12}^f Y_p + R_{13}^f Z_p + T_x}{R_{31}^f X_p + R_{32}^f Y_p + R_{33}^f Z_p + T_z} \\ y_p^f - \frac{R_{21}^f X_p + R_{22}^f Y_p + R_{23}^f Z_p + T_y}{R_{31}^f X_p + R_{32}^f Y_p + R_{33}^f Z_p + T_z} \end{pmatrix}$$

and C is the error covariance matrix. We will continue with the assumption that $C = I$.

Call the objective function $\Phi(u) = \epsilon(u)^T \epsilon(u)$ with u the vector of unknowns. Given a starting value for the vector of unknowns u we iterate with steps Δu by locally fitting a quadratic function to $\Phi(u)$

$$\Phi(u + \Delta u) = \Phi(u) + \Delta u^T \nabla \Phi(u) + \frac{1}{2} \Delta u^T \mathbf{H}(u) \Delta u,$$

where $\nabla \Phi$ is the gradient and \mathbf{H} is the Hessian of Φ . The minimum of this local quadratic is at Δu satisfying

$$\mathbf{H} \delta u = -\nabla \Phi(u).$$

If $\Phi(u) = \epsilon(u)^T \epsilon(u)$ then

$$\nabla \Phi = 2 \sum_i \epsilon_i(u) \nabla \epsilon_i(u)^T = \mathbf{J}(u)^T \epsilon,$$

where the Jacobian \mathbf{J} consists of elements

$$\mathbf{J}_{ij} = \frac{\partial \epsilon_i}{\partial u_j},$$

and the Hessian reads

$$\begin{aligned} \mathbf{H} &= 2 \sum_i \left(\nabla \epsilon_i(u) \nabla \epsilon_i(u)^T + \epsilon_i(u) \frac{\partial^2 \epsilon_i}{\partial u^2} \right) \\ &= 2 \left(\mathbf{J}(u)^T \mathbf{J}(u) + \sum_i \epsilon_i(u) \frac{\partial^2 \epsilon_i}{\partial u^2} \right) \approx 2 \mathbf{J}(u)^T \mathbf{J}(u) \end{aligned}$$

by omitting quadratic terms inside the Hessian. This yields the Gauss–Newton iteration

$$(\mathbf{J}^T \mathbf{J}) \Delta u = \mathbf{J}^T \epsilon,$$

involving the inversion of a $(6F + 3N - 7) \times (6F + 3N - 7)$ matrix. Bundle adjustment is about the *art* of inverting efficiently $(\mathbf{J}^T \mathbf{J})$.

Let us split the unknown vector u into $u = (a, b)$ following [32.48] obtaining

- $6F - 6$ motion unknowns a ,
- $3P - 1$ structure unknowns b ,

and we will explain this case better if we assume two motion unknowns a_1 and a_2 corresponding to 2 frames, and 3 unknown points b_1, b_2, b_3 .

For keeping symmetry in writing we do not deal here with the global reference and the global scale ambiguity.

The Jacobian for 2 frames and 3 points has 6 pairs of rows (one pair for each image projection) and 15 columns/unknowns

$$\mathbf{J} = \frac{\partial \epsilon}{\partial (a, b)} = \begin{pmatrix} \mathbf{A}_1^1 & 0 & \mathbf{B}_1^1 & 0 & 0 \\ 0 & \mathbf{A}_1^2 & \mathbf{B}_1^2 & 0 & 0 \\ \mathbf{A}_2^1 & 0 & 0 & \mathbf{B}_2^1 & 0 \\ 0 & \mathbf{A}_2^2 & 0 & \mathbf{B}_2^2 & 0 \\ \mathbf{A}_3^1 & 0 & 0 & 0 & \mathbf{B}_3^1 \\ 0 & \mathbf{A}_3^2 & 0 & 0 & \mathbf{B}_3^2 \end{pmatrix},$$

motion
structure

with \mathbf{A} matrices being 2×6 and \mathbf{B} matrices being 2×3 being Jacobians of the error ϵ_i^f of the projection of the i -th point in the f -th frame. We observe now a pattern emerging in $\mathbf{J}^T \mathbf{J}$

$$\mathbf{J}^T \mathbf{J} = \begin{pmatrix} \mathbf{U}^1 & 0 & \mathbf{W}_1^1 & \mathbf{W}_1^2 & \mathbf{W}_1^3 \\ 0 & \mathbf{U}^2 & \mathbf{W}_2^1 & \mathbf{W}_2^2 & \mathbf{W}_2^3 \\ \dots & \dots & \mathbf{V}_1 & 0 & 0 \\ \dots & \dots & 0 & \mathbf{V}_2 & 0 \\ \dots & \dots & 0 & 0 & \mathbf{V}_3 \end{pmatrix},$$

with the block diagonals for motion and structure separated. Let us rewrite the basic iteration $(\mathbf{J}^T \mathbf{J}) \Delta u = \mathbf{J}^T \epsilon$ as

$$\begin{pmatrix} \mathbf{U} & \mathbf{W} \\ \mathbf{W}^T & \mathbf{V} \end{pmatrix} \begin{pmatrix} \Delta a \\ \Delta b \end{pmatrix} = \begin{pmatrix} \epsilon'_a \\ \epsilon'_b \end{pmatrix},$$

and premultiply with

$$\begin{pmatrix} I & \mathbf{WV}^{-1} \\ 0 & I \end{pmatrix} \begin{pmatrix} \mathbf{U} & \mathbf{W} \\ \mathbf{W}^T & \mathbf{V} \end{pmatrix} \begin{pmatrix} \Delta a \\ \Delta b \end{pmatrix} = \begin{pmatrix} I & \mathbf{WV}^{-1} \\ 0 & I \end{pmatrix} \begin{pmatrix} \epsilon'_a \\ \epsilon'_b \end{pmatrix}$$

We find out that motion parameters can be updated separately by inverting a $6F \times 6F$ matrix

$$(\mathbf{U} - \mathbf{WV}^{-1} \mathbf{W}^T) \Delta a = \epsilon'_a - \mathbf{WV}^{-1} \epsilon'_b.$$

Each 3-D point can be updated separately by inverting a 3×3 matrix \mathbf{V}

$$\mathbf{V} \Delta b = \epsilon'_b - \mathbf{W}^T \Delta a$$

It is worth mentioning that bundle adjustment though extremely slow captures the correlation between motion estimates and structure (3-D points) estimates which is artificially hidden in the iterative scheme in (32.29).

The largest scale motion estimation and registration of views has been performed by *Teller et al.* [32.49] with a decoupled computation first of relative rotations

and finally of relative translations. The above multiple view SfM techniques can also be applied in a sliding window mode in time. *Davison et al.* [32.28] showed the first real-time recursive approach by decoupling the direction of the viewing rays from the depth unknowns. For other recursive approaches the reader is referred to the corresponding [SLAM](#) chapter.

32.2 3-D Vision for Grasping

In this section we will move from the basic geometry required for grasping to the main 3-D vision challenges associated with the limited knowledge we might have about the shape of the object as well as the actual selection of 3-D grasping poses.

Naturally, object grasping and manipulation is closely related to general scene understanding and problems such as object detection, recognition, categorization and pose estimation. Taking all the above, there are very few approaches that address all the problems in a single system. One example, reported in [32.50], addresses the problem of enabling transfer of grasp knowledge between object categories, defined using both their physical properties and functionality. This is a challenging problem given that a number of objects with similar physical properties afford different tasks. An example can be a screwdriver and a carrot that are structurally alike, but only the former can be used as a tool, or a ball and an orange where only the latter affords eating (Fig. 32.3).

In relation to object grasping in particular, there are methods that assume that full 3-D model of the object is available and concentrate on grasp synthesis solely. In addition, many of the approaches conduct experiments in a simulated environment without working with real sensory data. However, the knowledge generated in simulation can also be applied later onto sensory data. Another group of approaches considers grasp synthesis on real sensory data directly, dealing with problems such as noise, occlusions and missing data.

If the object to be grasped is known, there are approaches that store a database of grasp hypotheses, generated either in simulation or through experiments in a real setting. Most of the approaches assume that

a 3-D mesh of the object is available and the challenge is then to automatically generate a set of feasible grasp hypotheses. This involves sampling the infinite space of possible hand configurations and ranking the resulting grasps according to some quality metric.

To simplify the process, a common approach is to approximate object's shape with a constellation of primitives such as spheres, cones, cylinders, boxes or superquadrics [32.51–55]. The purpose of using shape primitives is to reduce the number of candidate grasps and thus prune the search space for finding the optimal set of grasp hypotheses.

One example, shown in Fig. 32.4 and reported in [32.52], decomposes a point cloud from a stereo camera into a constellation of boxes. Grasp planning is performed directly on the boxes which reduces the number of potential grasps. *El-Khoury and Sahbani* [32.56] distinguish between graspable and nongraspable parts of an object where each part is represented by fitting a superquadric to the point cloud data. *Pelossof et al.* [32.57] approximate an object with a single superquadric and use a Support Vector Machines based approach to search for the grasp that maximizes the grasp quality. *Boularias et al.* [32.58] model an object as a Markov random field (MRF) in which the nodes are points from the point cloud and edges are spanned between the six nearest neighbors of a point. A node in the MRF carries either one of the two labels: a good or a bad grasp location. *Detry et al.* [32.59] model the object as a constellation of local multimodal contour descriptors. The set of associated grasp hypotheses is modeled as a nonparametric density function in the space of six-dimensional (6-D) gripper poses, referred to as a *bootstrap* density. *Papazov et al.* [32.60] demon-

Fig. 32.3 Examples of physically similar objects that afford different tasks

Fig. 32.4 Generation of grasp candidates through object shape approximation and decomposition from (after [32.52])

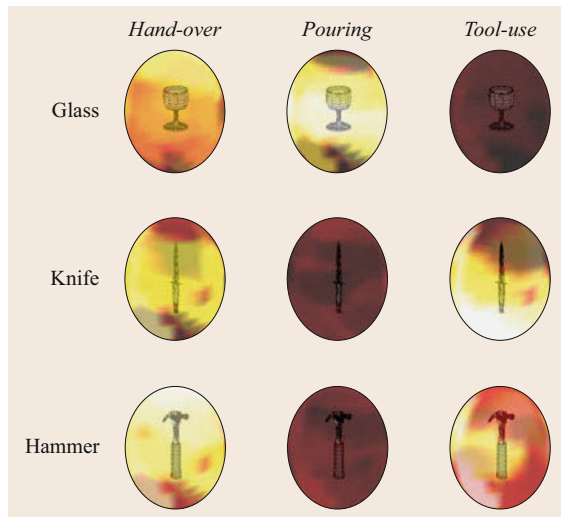

Fig. 32.5 Ranking of approach vectors on different objects given a specific task. The brighter an area the higher the rank. The darker an area, the lower the rank (after [32.62])

strates 3-D object recognition and pose estimation in a grasping scenario considering cluttered scenes. *Weisz* and *Allen* [32.61] proposes a metric suitable for predicting grasp stability under pose uncertainty.

There are several approaches that deal specifically with incomplete point clouds. *Marton* et al. [32.63] exploit symmetry by fitting a curve to a cross section of the point cloud. *Rao* et al. [32.64] concentrates on depth segmentation and sample grasp points from the surface of a segmented object using surface normals. *Bohg* et al. [32.65] presents a related approach that reconstructs full object shape assuming

planar symmetry and generates grasps based on the global shape of the object. *Bone* et al. [32.66] makes no prior assumption about the shape of the object and apply shape carving for generating a parallel-jaw gripper grasps. *Hsiao* et al. [32.67] employs heuristics for generating grasp hypotheses dependent on the shape of the point cloud. Recent work in [32.68] identifies regions that afford force closure grasps by evaluating local curvature of the objects to create an initial opposing grasp with two or three fingers, dependent on the relative size of the object with respect to the hand. *Richtsfield* and *Vincze* [32.69] uses a stereo-camera setup to generate a 3-D representation of a scene with several objects and then generates various top grasps on object candidates. *Maldonado* et al. [32.70] use time-of-flight range data, model objects using 3-D Gaussians and rely on finger torque information during grasping to monitor the grasp execution. *Stückler* et al. [32.71] generate grasp hypotheses based on eigenvectors of the object's *footprints* that are generated by projecting the 3-D object point cloud onto the supporting surface. The work of [32.72] presents a system for general scene understanding used for grasp planning and execution. The system uses a bottom-up grouping approach where contour and surface structures are used as the basis for grasp planning. The work builds upon previous work presented in [32.73].

Most of the recent work concentrates on grasp generalization either by observing human grasping or through off- and on-line learning directly on the robot. *Kroemer* et al. [32.74] demonstrates generalization capabilities using a pouring task scenario. The goal of the approach is to find a part of the object that is most likely to afford the demonstrated action. The learning method is based on the kernel logistic regression. *Herzog* et al. [32.75] stores a set of local templates of object that a human is interacting with. If a local part of an object segmented online is similar to a template in the database, the associated grasp hypothesis is executed. *Song* et al. [32.62] approach the problem of inferring a full grasp configuration in relation to a specific task the object is intended for. As in [32.76], the joint distribution over various grasping variables is modeled as a Bayesian network. Additional variables like task, object category and task constraints are introduced. The structure of this model is learned given a large number of grasp examples generated in a simulator and annotated with grasp quality metrics as well as suitability for a specific task. The learned quality of grasps on specific objects given a task is visualized in Fig. 32.5.

32.3 Conclusion and Further Reading

As main additional sources of reading, we recommend the textbooks by *Hartley and Zisserman* [32.12], *Ma et al.* [32.46], *Faugeras* [32.77], and *Faugeras and Luong* [32.11]. The reader is referred to Chap. 5 for fundamentals of estimation, to Chap. 35 for sensor fusion, to Chap. 34 for visual servoing, to Chap. 31 for range sensing, to Chap. 45 for 3-D models of the world, and to Chap. 46 for SLAM.

3-D vision is a rapidly advancing field and in this chapter we have covered only geomet-

ric approaches based on RGB cameras. Although depth sensors will become ubiquitous indoors and might be outdoors as well, RGB cameras remain formidable because of the higher number and larger diversity of features that can be matched and used for pose estimation and 3-D-modelling. Long range sensing can still be covered from motion with large translation while active sensors are constrained in terms of energy reflected from the environment.

33. Visual Object Class Recognition

Michael Stark, Bernt Schiele, Aleš Leonardis

Object class recognition is among the most fundamental problems in computer vision and thus has been researched intensively over the years. This chapter is mostly concerned with the recognition and detection of basic level object classes such as cars, persons, chairs, or dogs. We will review the state of the art and in particular discuss the most promising methods available today.

33.1 Object Classes

Generic object class recognition has been one of the goals of computer vision since its beginnings [33.1, 2]. In this context, it is important to emphasize that the notion and the abstraction level of object classes is far from being uniquely and clearly defined. Notably, the question of how humans organize knowledge at different levels has received much attention in cognitive psychology [33.3, 4]. Taking an example from Brown's work, a dog can not only be thought of as a *dog*, but also as a *boxer*, a *quadruped*, or in general an *animate being* [33.3]. Yet, *dog* is the term that comes to mind most easily, which is by no means accidental. Experiments show that there is a *basic level* in human categorization at which most knowledge is organized [33.5]. According to Rosch et al. and Lakoff [33.5, 6], this basic level is also:

- The highest level at which category members have similar perceived shape
- The highest level at which a single mental image can reflect the entire category
- The highest level at which a person uses similar motor actions for interacting with category members
- The level at which human subjects are fastest at identifying category members
- the first level named and understood by children.

Given that the basic level of categorization is easiest for humans, it should be a good starting point for machine vision, too [33.7]. The next lower level, *subordinate categories*, corresponds to the individual level used in object identification, e.g., the next higher level, *super-ordinate categories*, requires a higher degree of abstraction and world knowledge. The following will thus discuss state-of-the-art approaches first for basic-level categorization but then also briefly touch upon subordinate categorization for fine-grained classification.

33.2 Review of the State of the Art

One can think of all current methods in object class recognition as being part-based methods, in which object class instances are described by a set of parts (such as human body parts, for instance), and the topology between the parts (such as the kinematic tree defined by the joints that connect the human body parts). The following sections give a systematic treatment of different instantiations of state of the art, part-based methods, ranging from the bag-of-words model (Sect. 33.2.1) and spatial pyramid matching (Sect. 33.2.2), over flexible part models (Sect. 33.2.3) and rigid histogram of oriented gradients templates (Sect. 33.2.4) to deformable part models (Sect. 33.2.5) and convolutional neural networks (Sect. 33.2.6). Table 33.1 summarizes the various part-based methods presented in this section. Later sections highlight recent trends in fine-grained categorization (Sect. 33.2.7) and datasets for visual recognition (Sect. 33.2.8).

Table 33.1 Classification of some prominent approaches as part-based models

Model	Parts	Topology
Bag-of-words	Feature clusters	No spatial information coded
Spatial pyramid	Feature clusters	Hierarchical but rigid spatial grid
Constellation model	Feature clusters	Full covariance matrix between clusters
Implicit shape model	Feature clusters	Star-shaped model
HOG	HOG-cells	Rigid spatial grid
DPM	HOG-parts	Star-model
Pictorial structures model	Semantic parts	Tree structure
Convolutional neural networks	Convolution filters	Spatial spooling and hierarchy

33.2.1 Bag-of-Words Models

Apart from allowing to establish pointwise correspondences between multiple images of the same scene, local image patches also provide the foundation for a variety of object class representations for visual recognition. Inspired by the natural language processing literature, the *bag-of-words* (BOW) or *bag of features* model [33.8] represents an image as an unordered collection (a bag) of local patches. This representation assumes that most of the important information about the image content is captured purely by which patches occur (and how often), irrespective of where they occur. While this is clearly an approximation, it seems reasonable from the text document analogy: even if the words in a text document are shuffled randomly, the mere occurrence of certain key terms provides a strong cue about the document’s topic. Likewise, a collection of local image patches, such as two eye patches, mouth, and nose, provide strong cues for the presence of a face in an image.

The bag-of-words model is typically based on a codebook of visual words: a fixed, discrete set of visual features relative to which all others are described (Fig. 33.1c). An input image (Fig. 33.1a) can then be described relative to that codebook, by counting how often each codeword appears (Fig 33.1b). In the following paragraphs, we describe in detail the extraction of visual features, the generation of codebooks of visual words, and their use in image classification using probabilistic generative and discriminative models.

Feature Extraction

Locations and scales for feature extraction are typically either picked sparsely, based on an interest operator, such as the difference of Gaussian (DOG)

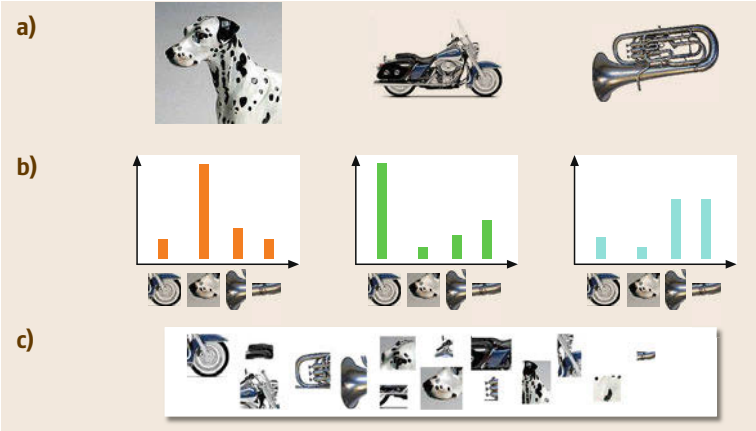

Fig.33.1a–c The bag-of-words representation. (a) Image; (b) BOW histogram; (c) codebook of words

interest point detector for scale invariant feature transform (SIFT) [33.9], Harris corners, scale- and affine-invariant Hessian–Laplace interest points [33.10], maximally stable extremal regions (MSER) [33.11], or based on dense feature sampling using a fixed spatial grid [33.12]. While interest operators generally provide well-localized, repeatable features with sufficient recall, the increasing availability of compute power today has made very dense feature sampling feasible (e.g., with a stride of only one pixel, resulting in many thousands of features in an image) – in the limit, dense sampling typically outperforms sparse interest operators in image classification as interest point detectors are designed to sample particular types of image structure whereas dense sampling allows to sample any type of image structure (note that this might be different for other applications, such as structure from motion, in which it is more important to find smaller numbers of features with high precision).

Codebook Generation

Codebooks of visual features are typically constructed by applying an unsupervised clustering algorithm, such as *k*-means or hierarchical agglomerative clustering [33.13], to a training set of image feature vectors. The result is a vector-quantized representation of the visual feature space that groups similar feature descriptors into clusters. Each cluster thus effectively generalizes over its members, such that small visual differences are suppressed – this is often seen as a crucial trait for categorization even though larger codebook sizes typically result in better performance. Each cluster is identified with a representative member, i.e., its centroid (for *k*-means) or medoid (for agglomerative clustering). In order to represent a new image with respect to the generated codebook, image features are extracted, and matched to the representative of each cluster (e.g., by computing pairwise distances and defining a matching threshold). The result of this matching is then recorded (e.g., as a histogram over the number of times each cluster has been matched) to yield the image or object representation. Note that in the context of BOW models the terms object and image representation are synonymous.

For codebook generation, the number of clusters is an important free parameter: it has been found that large codebook sizes typically improve recognition performance, since they represent the original feature space more faithfully, with lower reconstruction error. On the other hand, large codebooks generalize less, and come at the cost of increased computational cost when building bag-of-words representations and classifying them with nonlinear classifiers. Typically, codebooks with several and even 10 000s (multiples of ten thousand) of clusters are chosen for optimal performance [33.14].

Generative Models

Inspired by their success in the text domain, generative probabilistic models have also been adopted for image classification in connection with BOW representations. The arguably simplest one is the naive Bayes model [33.8, 15], in which the posterior probability of an image having a certain class factors into independent contributions from each histogram bin (i.e., for a given class, knowing about the presence of one feature does not make the presence of another feature any more or less likely). While this model is agnostic of correlations that often exist between features (for instance, having already observed two wheel features in a sideview of a car makes it unlikely to observe one more, assuming that only a single car is present in the image), it often works well in practice and is appealing due to its simplicity.

In line with the text domain, more powerful models have been proposed for image classification that explicitly capture the co-occurrence of features through a generative process. Here, the features contained in an image are assumed to be generated in a sequence of steps, where each step determines the choices available for the next step. More precisely, each step is implemented by sampling from a probability distribution, conditioned on the outcome of the previous step.

A popular class of generative models is the *topic model* [33.16, 17]: an image is considered to be an orderless document of visual words, composed of multiple topics (in an image depicting a beach scene, there could be a water topic, a sand topic, and a sky topic, for instance). In order to generate a particular feature in the image, a topic is first sampled from a discrete distribution over topics (a beach scene could be a roughly uniform distribution over water, sand, and sky). Then, a visual feature is sampled from a discrete distribution over features, conditioned on the previously sampled topic (e.g., for a water topic, the sampled feature is likely to be a blue image patch with a ripple pattern). In practice, the assignment of visual features to topics is represented through latent variables, which means that it has to be inferred from other quantities that can be observed (such that the likelihood of the features is maximized). This is typically implemented by means of the expectation maximization (EM) [33.18] algorithm, which alternates (re-)estimation of topic distributions (E-step) and imputation of latent variables (M-step) in an iterative procedure.

In the literature, there exists a large variety of topic models, ranging from the basic probabilistic latent semantic analysis (PLSA) [33.16] over its Bayesian extension, latent Dirichlet allocation (LDA) [33.17], to

Fig. 33.2 Spatial pyramid matching as a multilevel BOw representation (after [33.20])

infinite hierarchical models of images and their features [33.19].

Discriminative Models

Once an image is represented as a histogram of matched features with respect to a codebook, it can be classified by means of any discriminative classifier that is applicable to histograms. Popular choices include support vector machines [33.21] with histogram intersection kernels or their approximate counterpart [33.22], boosting [33.23], or random forest classifiers [33.24].

Extensions

While the bag-of-words representation inherently ignores spatial information, it can be re-introduced by restricting the support of a bag-of-words representation to a local image region, and processing multiple regions independently. Specifically, instances of an object class can be localized by sliding a rectangular window over the image under consideration, extracting a bag-of-words representation at each location, and feeding the result into a classifier that distinguishes the object class of interest from a background. Objects of different sizes can be localized by applying this scheme to multiple re-scaled versions of the input image [33.25] (called an image pyramid).

Rather than applying the sliding window in a brute force fashion, it has been realized that the classifier score that an image window can attain can be bounded from above by the scores of the subwindows that it contains. This observation gives rise to an efficient subwindow search [33.26] that greatly reduces the number of classifier evaluations needed in connection with sliding window bag of words representations, making powerful but slow nonlinear kernel SVMs applicable.

33.2.2 Spatial Pyramid Matching

Instead of completely ignoring the spatial layout of local features in an image, it seems reasonable to include at least a rough notion of locality in order to increase the discriminative power of an object class representation. Spatial pyramid matching implements this notion as an extension of the bag-of-words model (Sect. 33.2.1), by extracting multiple bag-of-words representations for a single input image at different spatial

locations and scales, and aggregating these local representations into a single global representation for the entire image. Specifically, spatial pyramid matching (SPM) [33.27] extracts bag-of-words histograms for each cell in a rectangular grid overlaid onto the input image (typically, coarse grids of 2^l for $l \in \{0, 1, 2\}$). This process is repeated multiple times with different numbers of cells (e.g., four by four plus two by two plus a single cell), forming an overcomplete pyramid structure of decreasing spatial resolution (Fig. 33.2). The resulting bag-of-words histograms for each cell are concatenated (and re-normalized). The appeal of SPM lies in representing the spatial layout at multiple levels of resolution without committing to any one in particular – instead, the representations of all resolutions are kept, and have the chance to contribute to image classification in case they prove useful.

The basic SPM methodology appears in numerous variations in the literature, but often follows the same pipeline of four steps (feature extraction, feature coding, spatial pooling, and classification), each of which we review in the following sections.

Feature Extraction

Like the basic bag-of-words model, the SPM model has been used in connection with various feature types, ranging from SIFT [33.9] appearance features to local edge configurations [33.28] and self-similarity features [33.29].

Feature Coding

Representing visual features relative to a pretrained codebook obtained by vector quantization is only one special case of feature coding (performing a change of representation), and several improvements have been proposed in the literature [33.30–32]. Most importantly, it has proven beneficial to explicitly formulate the codebook training and feature coding as a joint optimization problem, such that the original features can be reconstructed with small error from their respective codes. In addition, this formulation allows us to relax the assumption that each feature is matched to exactly one codebook entry by replacing the cardinality constraint with an L1 regularization. The resulting sparse coding (SC) formulation [33.31] has been shown to outperform the original SPM [33.27] by significant margins, even

when combined with a linear **SVM** (while **SPM** works best in connection with nonlinear histogram intersection or chi-square kernels, which are computationally expensive). An improved version of **SC** is given by locality constrained linear coding (**LLC**) [33.32]. It replaces sparsity by locality constraints that encourage features to be reconstructed by nearby features in feature space, such that similar features yield similar codes (which is obviously desirable in order to facilitate classifier learning).

Instead of relying solely on counting the number of occurrences of visual features in a spatial region as promoted by **SPM**, **SC**, and **LLC**, the Fisher vector [33.30] method characterizes that region by how well a pretrained generative probabilistic model (a Gaussian mixture model, **GMM**) explains the contained features. Specifically, it builds a vector from the derivatives of the log-likelihood of the image features, given the mixture coefficients, means, and diagonal covariances of a **GMM**. Note that this vector has much more entries than a histogram of occurrences using the same **GMM** as a codebook, allowing to build highly discriminative representations already for small numbers of **GMM** mixture components (typically only a few hundred).

Both sparse coding and Fisher vector representations have proven to be very effective for image classification in connection with spatial pyramids, and have been successfully applied also in large-scale settings, such as classification on ImageNet [33.33] (Sect. 33.2.8).

Spatial Pooling

Apart from the classic pyramid scheme [33.27] in which histograms of different pyramid levels are concatenated, retaining the maximum value of a particular bin over a spatial region or even multiple pyramid levels (max-pooling) has gained increasing attention [33.31], in particular in connection with **CNNs** (Sect. 33.2.6). Max-pooling has the advantage that it promotes invariance to local translations and scale changes, and has been found to be present in the human visual cortex (V1) [33.34].

In addition to pooling features in the two-dimensional (2-D) image plane, more object-centric pooling techniques have been developed in the context of fine-grained categorization [33.35, 36] (Sect. 33.2.7).

Classification

The last stage in an **SPM** pipeline is typically given by a discriminative classifier that is trained on a training set of fixed length vectors created from the **SPM** representations. Depending on the sophistication of the feature coding step, support vector machines with nonlinear histogram intersection or chi-square [33.27] or

linear kernels [33.30–32] achieve state-of-the-art performance. Further extensions include the use of multiple kernels with learned contribution weights [33.37]. When evaluated as part of a classification cascade, multiple kernel learning (**MKL**) can also be used in a sliding window object class detector [33.38].

33.2.3 Flexible Part Models

While orderless bags of visual features (Sect. 33.2.1) or spatial pyramids with a fixed grid layout (Sect. 33.2.2) have proven to be effective object class representations for classification, they both fail to explicitly capture the flexible nature of physical objects that are composed of multiple parts – as an example, consider the human face with eyes, eyebrows, mouth, nose, and ears: obviously, the precise shape and spatial arrangement of these parts will vary from person to person, but variations in shape and arrangement are constrained to lie within a plausible range (i.e., the parts are not unordered as in a bag-of-words representation). It also seems intuitive that the constraints that govern the range of plausible variations should be soft, and not bound to a fixed binning or a fixed spatial grid (as in spatial pyramid matching). In this section, we review a family of flexible part models that implement this intuition.

Constellation Model

The constellation model [33.39–41] represents an object class as a flexible arrangement of a fixed number of parts. It consists of two components: first, a model of the appearance of each part, and second, a model of the relative spatial layout of the parts. It is formulated in a fully probabilistic way, such that each part is characterized by a probabilistic, generative model of its appearance, and the spatial layout of the parts is governed by a joint Gaussian distribution that captures how the location (and scale) of each part is expected to vary with the location of each other part. Interestingly, the definition of what constitutes a part is driven entirely by the training data: parts are chosen and placed such that the likelihood of the training data, given the model, is maximized during training. This can be seen as an instance of a missing data problem (the association between features and parts is unknown), and solved by means of the expectation maximization (**EM**) algorithm.

Unfortunately, the representative power of the joint Gaussian spatial distribution comes at a cost: the fully connected dependency structure demands examining each of the exponentially many combinations of placing all parts in an image in order to find the global optimum – the exact inference problem is known to be intractable. As a consequence, the original constellation

model [33.40, 41] is limited to a few dozen candidates per part, per image, limiting its generality. An alternative approach to solving the exact inference problem is to resort to an approximation, e.g., by sampling likely constellations from part detection proposals [33.42]. In this way, the number of part candidates can be scaled up to several thousands.

Due to its probabilistic nature, the constellation model has also been extended to a full Bayesian model [33.43], in which the object class model itself is governed by a prior distribution over models. This abstraction allows to separate characteristics of one particular object class (e.g., the particular shape of a horse's head) from properties that are shared by classes (e.g., all quadrupeds are four legged). These shared properties can be re-used in multiple object class detectors (e.g., for horses, cows, dogs, etc.), facilitating learning from limited training data. The underlying idea of re-use of information is known as transfer learning in the machine learning literature, and has been successfully applied for image classification [33.43] as well as object class detection.

Implicit Shape Model

The implicit shape model (ISM) [33.44] relaxes the assumption of the constellation model that the locations and scales of all parts are mutually dependent. Instead, it limits the dependency structure to a star topology, in which part locations and scales are conditionally independent, given the object center (i.e., given the object center, revealing information about the location of one part does not alter the expectation of where to observe any other part). While this model clearly constitutes an approximation of the physical world, it greatly simplifies the inference problem of finding the configuration with maximum score (there exists an algorithm that is exact and efficient).

Specifically, the ISM represents an object class as a collection of local feature matches – the supply of matchable features is given by a codebook of visual words, as it is also used in bag-of-words (Sect. 33.2.1) or spatial pyramid representations (Sect. 33.2.2). In contrast to those, however, each ISM codebook entry also maintains a list of feature matches from a training set of images: each match specifies where the match occurred relative to the object center. As a result, this list of occurrences constitutes a nonparametric probability density estimate of the location of the object center, given the matched feature – in other words, each feature can cast votes for likely object center positions (e.g., a wheel feature can cast two votes: one to the left of it, assuming that it is the front wheel of a car, and one to the right, assuming it's the back wheel). This voting

procedure can directly be translated into a recognition algorithm: at recognition time, all test image features cast their votes into a three-dimensional (3-D) voting space (x , y , and scale). All votes are accumulated, and since multiple features are likely to agree on the true object center, the maxima of this voting space can be considered candidate object detections (note that this voting can be considered a generalized Hough transform). In practice, continuous voting space maxima are found using a mean-shift algorithm.

In order to increase its discriminative power, the basic ISM model is extended by a verification step [33.44], in which object detection candidates are verified based on how consistent they are with respect to foreground–background segmentation. To that end, feature occurrences stored as part of the codebook are enriched with segmentation mask fragments (which have to be provided as additional supervision during training). At recognition time, the consistency of the cast segmentation mask votes is quantified based on minimum description length (MDL). In addition, it has been suggested to learn weights that regulate the contributions of feature matches to the final detection hypotheses in a discriminative way (i.e., optimized to distinguish object and background firings). This *discriminative Hough transform* [33.45] further improves the performance of the ISM and constitutes the basis for the *poselet* framework [33.46], in which a multitude of small HOG [33.47] detectors (Sect. 33.2.4) are combined in order to detect people.

Since, in theory, the ISM voting space can accommodate arbitrary quantities in addition to object center and scale, there have been extensions to predict the walking poses of pedestrians [33.48] as well as predicting the viewpoint from which the detected object is imaged [33.49, 50].

Pictorial Structures

While being the first to conceptualize the idea of objects being composed of flexible parts, the pictorial structures model [33.39, 51] is typically understood as a simplified version of the constellation model. The full mutual dependency structure between parts is relaxed to a tree (or a mixture of trees in more advanced incarnations) – note that the star-shaped ISM (Sect. 33.2.3) is hence a special case of a pictorial structures model with tree-depth one. In contrast to the constellation model, where parts are defined in a data-driven way, the pictorial structures model is typically associated with a semantic notion of parts. An intuitive example is the set of human body parts (head, torso, upper arm, lower arm, etc.) in connection with the natural kinematic tree structure (Fig. 33.3).

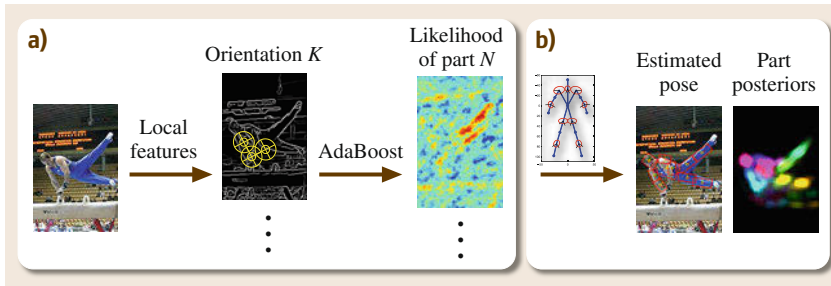

Fig.33.3a,b Human body pose estimation with the pictorial structures model. **(a)** Image likelihoods for individual parts; **(b)** final pose estimate using spatial layout prior

In fact, current state-of-the-art systems for people detection and human body pose estimation are typically built upon the pictorial structures model [33.52]. Here, pairwise relations between body parts express the angular constraints of the human body as well as the prior probability of observing people in various poses (e.g., it is unlikely to observe extreme angles at certain joints, Fig. 33.3b). In order to compensate for the weaker spatial model in comparison to the constellation model, the pictorial structures model typically relies on a strong model for the appearance of each part that is trained discriminatively (distinguishing the part from background, Fig. 33.3a) rather than in a generate way (explaining the part's appearance). Examples of discriminative part appearance models include AdaBoost [33.23] classifiers trained on dense shape context features [33.52]. Also note that part appearance and spatial layout models are trained independently (joint training has been realized to bear large potential for improvement in the context of the deformable part model [33.53] which we will review in Sect. 33.2.5).

The use of semantic parts naturally demands to provide additional supervision in the form of part annotations during training; human body parts are typically annotated with a fixed size relative to the size of the person. For recognition, inference in the tree-structured probabilistic graphical model can be carried out exactly and efficiently by max-product or sum-product belief propagation, depending on whether the maximum a posteriori (MAP) or marginal solution is preferred.

Extensions to the pictorial structures model include learning the tree structure instead of using the natural kinematic tree [33.54], introducing additional lateral edges in addition to the tree edges [33.55], and combining pictorial structures models with non-parametric representations of partial human poses (*poselets* [33.46]).

33.2.4 Histogram of Oriented Gradients

At the opposite end of the spectrum from the bag-of-words (Sect. 33.2.1) or flexible part models (Sect. 33.2.3) are approaches that represent an object

class as a rigid template of local features with a fixed spatial layout. Conceptually, this corresponds to the finest level of a spatial pyramid in which each feature gets assigned its own exclusive set of histogram bins (with values equal to the feature itself). The by far most successful rigid template detector is the histogram of oriented gradients (HOG) [33.47] detector, and we will discuss its properties in detail in this section. Originally developed for people detection, the HOG feature has evolved into one of the most frequently used features in computer vision to date, and also constitutes the basis for the successful deformable part model (DPM) [33.53] described in Sect. 33.2.5.

Feature Extraction

The HOG feature can be seen as an extension of SIFT [33.9] from a single circular interest region to a rectangular detection window – at its core, it bins gradient directions into histograms, weighting their contributions by their respective magnitudes. Like SIFT, it has been carefully engineered and its parameters empirically tuned for performance (more recently, learning features end-to-end has received renewed attention, Sect. 33.2.6).

The first step for the computation of a HOG feature is to divide the detection window into a fixed grid of cells: a cell is the basic spatial unit of measurement for the HOG feature. The second step is to gamma-normalize the pixel content of each cell, in order to increase robustness to lighting changes. Third, the image is smoothed and image gradients computed using discrete derivative masks. Fourth, gradients are binned, such that each gradient casts weighted votes (by magnitude) according to nine different gradient orientation bins. Votes are interpolated bilinearly in both orientation and position. And fifth, the per-cell histograms are contrast normalized with respect to a larger block of surrounding cells in order to compensate for local variations in lighting and foreground–background contrast. Crucially, blocks are formed such that they overlap, which means that each cell contributes multiple times to the final feature descriptor, normalized in different ways, resulting in an over-complete represen-

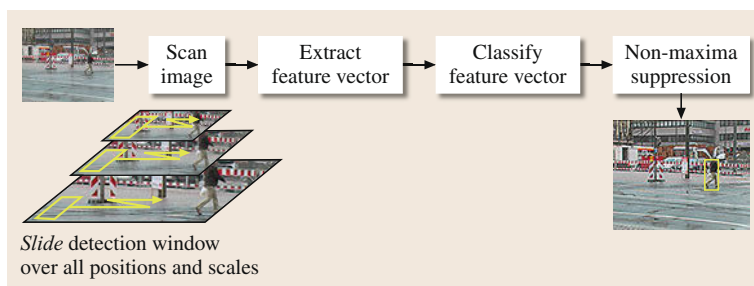

Fig. 33.4 Sliding window object class detection

tation. This step has been found to be essential for good performance.

Sliding Window Object Detection

Similar to pure bag-of-words and spatial pyramid-based detectors, the **HOG** detector is typically run in a sliding window fashion over a test image, over different locations and scales (Fig. 33.4). That is, **HOG** features are computed for a detection window of fixed size, resulting in a feature vector that can then be fed into a discriminative classifier, such as a linear support vector machine (**SVM**).

Bootstrapping

One of the key ingredients for good detection performance of the **HOG** detector [33.47] is a technique termed as *bootstrapping* (not to be confused with a technique of the same name known from statistics, in which a dataset is repeatedly subsampled). An initially trained model is refined by re-training it on an extended set of negative training images, similar in spirit to boosting [33.23]. Specifically, the initial model is run on a validation set, and the false positive detections (wrongly detected objects) are added to the negative training set. As a result, the decision boundary of the re-trained classifier is pushed further away from these *hard negatives*. Note that this procedure is not guaranteed to always lead to an improvement, but often improves performance substantially in practice.

Extensions

Due to its simple grid structure, the **HOG** feature lends itself to being combined with other feature channels ex-

tracted from a similar spatial grid. Notably, it has been successfully combined with optical flow features for people detection in video [33.57].

33.2.5 The Deformable Part Model

The section provides an introduction to one of the most successful computer vision algorithms to date, the **DPM** [33.53]. Its success is partly due to its consistently high performance for detecting a wide variety of object classes, but also due to the fact that a high quality implementation has been made publicly available from the start. The original implementation has constantly been improved and updated, and even found its way into OpenCV [33.58]. The **HOG** [33.47] implementation at its core has found wide spread use throughout the computer vision community.

Model Structure and Inference

The **DPM** can be seen as a proper generalization of the fully rigid **HOG** [33.47] template to a flexible, part-based object class representation (Fig. 33.5). It generalizes **HOG** in two different ways that both increase its ability to handle intraclass variation: first, it divides the single **HOG** template into a collection of multiple templates that can move relative to one another and capture small variations in object shape (hence the name *Deformable Part Model*). Specifically, it includes a low-resolution *root* template for the entire object plus a number of high-resolution *parts* that are constrained to occur not too far from their expected positions relative to the root – this constitutes a star-shaped probabilistic graphical model (**PGM**) in full analogy

to the implicit shape model [33.44] (Sect. 33.2.3) or a special case of a tree-structured pictorial structures model [33.39] (Sect. 33.2.3). While this is less powerful than a full constellation model [33.41] in terms of representation, it has proven very effective in connection with a discriminative learning regime.

Second, the **DPM** is formulated as a mixture model with multiple components, where each component takes care of another aspect of the object class of interest, such as a particular viewpoint or a particular context in which the object occurs (e.g., a person sitting on a chair). Each component consists of a star-model with root and multiple part templates as described earlier, trained to respond the strongest to its dedicated aspect – this separation of concerns leads to a simpler learning problem than trying to handle all aspects with a single component.

For recognition, each of the **DPM** components produces a score as follows: first, all of the component's templates (root and parts) are convolved with the image in a sliding window fashion, as in the original **HOG** [33.47] work (Sect. 33.2.4), resulting in dense score maps over image locations and scales. Second, root and part scores are combined with spatial deformation terms that reflect the star-shaped spatial dependency structure, resulting in new score maps over locations and scales – note that this inference step can be carried out by max-product belief propagation, which is exact and efficient due to the star topology, and implemented as an instance of a generalized distance transform [33.59]. And third, for each image location and scale, the maximum response over all components is kept as the final detection score (which is then further processed by a standard, greedy nonmaxima suppression).

Learning

It has been argued that much of the **DPM**'s excellent detection performance is due to the specific way in which parameters are learned from training data, in addition to the added expressive power in comparison to a single, rigid **HOG** template. This learning also constitutes the major difference between the **DPM** and earlier flexible part models such as the **ISM** [33.44] or the pictorial structures model [33.39] (Sect. 33.2.3) that are structurally equivalent, but less effective in terms of performance.

In contrast to these earlier models, where local part appearance and spatial layout models are trained separately, all **DPM** parameters are learned jointly, such that a single binary classification objective is optimized (distinguish between the object class of interest and background). Crucially, this includes the placement of parts relative to the root template as well as the

selection of the mixture component that is deemed responsible; both are treated as latent variables at training (and test) time. As a consequence, all aspects of the **DPM** are optimized towards the single goal of object class detection, without being convoluted by potentially suboptimal choices of part placement based on appearance similarity (**ISM**) or semantic meaning (pictorial structures).

The joint optimization problem is phrased as a generalization of the linear **SVM** [33.21] formulation of a single **HOG** template, termed latent support vector machine (**LSVM**) [33.60]. It is based on the following intuition: assuming that the latent variables (part placements and mixture component selection) are observed, all model parameters (**HOG** template and part displacement weights) can be learned using standard linear **SVM** procedures (the resulting objective function is convex, assuming the use of a hinge loss). Conversely, assuming known model parameters, the optimal values of all hidden variables can be found exactly and efficiently (using the distance transform for part placement and exhaustive search over components). This intuition gives rise to an **EM**-like alternation of two steps, which can be shown to converge to a local optimum of the original, nonconvex objective function.

Naturally, a good initialization is needed in order to reach good local optima during learning. The **DPM** suggests a clustering of training examples based on aspect ratio, which has proven to work surprisingly well in practice (clustering based on appearance typically results in small improvements but is much more costly in terms of computation time). As for the **HOG** detector [33.47], bootstrapping (here called *hard negative mining*) allows to escape bad local optima.

While the concept of jointly optimizing part appearance and placement has already existed in the constellation model [33.41], the **DPM** achieves this goal by largely different technical means, resulting in better performance: (1) it uses sliding-window **HOG** templates with linear **SVM** classifiers instead of a generative model over local interest point descriptors to represent local appearance, and (2) it relaxes the fully connected probabilistic graphical model topology to a star, making exact inference tractable and efficient for learning. The **DPM** has achieved excellent performance on a wide variety of benchmark datasets, including PASCAL **VOC** (visual object class) [33.61] (Sect. 33.2.8).

Multiview and 3-D DPMs

While the original **DPM** [33.53] achieves remarkable performance on standard detection benchmarks, it is inherently limited to predicting 2-D bounding boxes. While this might be sufficient for some applications (such as counting the number of objects in an image), it

is clearly not enough for others: suppose an autonomous driving scenario in which vehicles are to be tracked across multiple frames, and their spatial extent to be estimated in order to avoid collisions – here, a 3-D representation of each vehicle is required.

To that end, the DPM has been extended [33.56, 62, 63] to output richer object hypotheses than 2-D bounding boxes, in the form of additional viewpoint estimates (providing a better notion of 3-D object extent than a 2-D bounding box alone) and 3-D parts that are consistent across viewpoints (providing a basis for establishing correspondences across multiple frames in a sequence). Providing these richer outputs can be achieved by extending the original DPM in two different ways: first, the classification problem solved during learning can be reformulated as a structured output prediction problem [33.62]. In this way, the model can be optimized for the prediction of other quantities than a binary object-background label, such as 2-D bounding box overlap or angular viewpoint estimates, through the use of different loss functions. In its simplest variant, viewpoint estimation can be implemented by a binning of angles, and dedicating a single DPM mixture component to each angular bin. While this model is still inherently view-based, it has been shown to deliver excellent performance in both 2-D bounding box localization and viewpoint estimation (note that viewpoint labels have to be available during training in addition to bounding box annotations).

Second, instead of parameterizing the DPM parts in the image plane, an object-centric 3-D coordinate system can be used, such that parts from different mixture components refer to the same 3-D object portion (Fig. 33.6a). Part deformations are then governed by 3-D displacement distributions (Fig. 33.6b), and object as well as part appearance can be captured in a continu-

ous appearance model (Fig. 33.7a). The result is a 3-D object class representation [33.63] that can synthesize previously unseen viewpoints at test time (by interpolating between a number of supporting viewpoints for which training data is available) and thus estimate viewpoints up to arbitrary granularity. The learning of this 3-D object class representation is facilitated by using 3-D computer-aided design (CAD) models of the object class of interest in addition to real-world images (Fig. 33.7b). During training, the CAD models serve both to establish a 3-D coordinate system and to generate artificial training data for different viewpoints through rendering. Figure 33.8 shows example detections obtained by the 3-D²PM.

Computational Considerations

Interestingly, it has been realized that the major computational bottleneck of the original DPM [33.53] at recognition time is the convolution of HOG templates with image features (and not probabilistic graphical model inference as one might think). As a consequence, there have been attempts to minimize the number of HOG convolutions by various means, e.g., by part sharing across components and object classes [33.64], re-using parts of templates by decomposing them into an overcomplete set of dictionary elements [33.65] or cascaded detector evaluation [33.66]. Likewise, there have been attempts to reduce the training time for the DPM by exploiting HOG feature statistics to re-use computation across models [33.67, 68].

33.2.6 Convolutional Neural Networks

While artificial neural networks (ANNs) [33.69] had largely been neglected in favor of support vector machines, random forests, and other learners until around 2010, they have recently returned to the scene, with quite remarkable success. Among a number of artificial

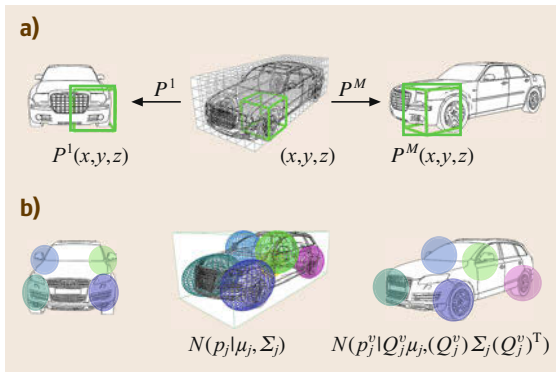

Fig.33.6a,b Part representation in the 3-D deformable part model (3-D DPM). (a) 3-D/2-D part coordinate systems; (after [33.62]) (b) 3-D/2-D part spatial distributions (after [33.63])

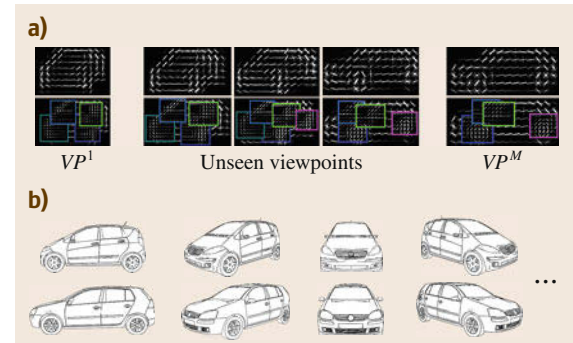

Fig.33.7a,b Continuous appearance model (a) in the 3-D²PM, trained from rendered 3-D CAD models (after [33.63]) (b) and real images (not shown)

neural network architectures that had been suggested already in the early days of computer vision, the convolutional neural network (CNN) [33.70] has emerged as a particularly promising candidate for becoming a standard tool for visual recognition tasks.

One of the key properties of the CNN is its specific structure (Fig. 33.9), which is both amenable to dealing with multidimensional input (such as a color image) and effective for preventing overfitting when learned from limited training data. As an ANN, a CNN defines an artificial neural network with multiple layers on an input image, such that image pixels provide the input to the neurons of the first layer, and the outputs of each layer of neurons provide the inputs to the next layer (the final layer can provide a task specific output, such as an encoding of different image classes). Now, the topology of the CNN is restricted in two specific ways: first, neurons in one layer can only be connected to a fixed spatial region of neurons in the preceding layer (the *receptive field*) – this dramatically reduces the total number of connections in the network and hence parameters of the model that have to be learned. And second, most layers of neurons (typically the lower layers) are formed by replicating local groups of neurons multiple times, including the weights associated with their connections to the preceding layer (*weight sharing*) – this further reduces the number of parameters of the model, and encourages the network to learn a representation for the input that is invariant to translation. As a result of their specific structure, CNNs are less prone to overfitting than fully connected ANNs, and can be successfully trained using gradient-based methods and back-propagation of errors.

CNNs for Image Classification

CNNs have recently achieved remarkable performance in large-scale image classification [33.71], fueled by the availability of large-scale datasets like ImageNet [33.33] that provide thousands of images per object class. The success of CNNs in image classification is mostly attributed to their ability to learn useful image representations end-to-end (*deep learning*) rather than relying on engineered features, such as SIFT [33.9] or HOG [33.47]. While the latter have been carefully designed and empirically tuned over many years, they are *general purpose* and not specifically adapted to the classification task at hand, and hence suboptimal. A recent study provides further insights into the operation of individual CNN components (hidden layers and classifiers) through visualization [33.74], resulting in a further boost in performance.

Region Proposals for Detection

Since the evaluation of a CNN is computationally expensive due to convolutions, a CNN is typically applied to preselected candidate regions rather than in a dense sliding window fashion for detection. Candidate regions can be generated either by a specialized detector trained for the object class of interest (such as HOG [33.47], Sect. 33.2.4) that is weaker but also much faster to evaluate than the CNN, or by a more general attention mechanism that generates bounding boxes that are likely to contain an object instance of *any* class. Among various methods that generate proposal regions with a high degree of *objectness* [33.75] ([33.76] for a recent discussion and analysis of region proposal methods), selective search [33.77] has been successfully used in

Fig. 33.8 3-D²PM example detections (car, bicycle, human head, cell phone)

Fig. 33.9 The CNN model of (after [33.71]) in the implementation of Caffe (after [33.72, 73])

connection with CNN-based, object class specific classifiers for detection [33.78]. Selective search is built upon a superpixel-based oversegmentation of an image, and suggests a greedy procedure to group adjacent superpixels into regions of high objectness. The resulting detector [33.79] has been shown to outperform previous results in generic object class detection by a large margin (notably outperforming the previous best results of the DPM [33.53], Sect. 33.2.5, on PASCAL VOC [33.61], Sect. 33.2.8). Curiously, it is not necessary to train this detector end-to-end for the task of object class detection for good performance – instead, the lower layers of the CNN can be pretrained for classification on ImageNet as in [33.71], and later fine-tuned for detection. Both the CNN pretrained on ImageNet and the resulting state-of-the-art object class detector are publicly available under the name *Caffe* [33.72] and likely to find their way into the toolboxes of many computer vision practitioners.

Structured Outputs

While artificial neural networks can represent any function in theory, effective learning of ANNs with more complex, structured outputs than single class labels or continuous values remains a challenge. Instead of learning a full network end-to-end, structured outputs are typically obtained by feeding the outputs of the last layer of neurons into an existing structured model, such as multiple body joint regressors for human body pose estimation [33.80].

33.2.7 Fine-Grained Categorization

In recent years, there has been a growing interest in distinguishing objects not only with respect to basic-level categories [33.5] (such as car, bicycle, and person), but also on a finer level of granularity (such as different car models or plant and animal species). This *fine-grained categorization* is deemed particularly challenging: the distinction between two categories is often determined by small visual differences (such as the shape of a car's headlight): these differences are easily outweighed by appearance differences due to change in lighting or viewpoint (a car looks largely different from the front and from the side), bearing the risk of overfitting to irrelevant details.

Feature Selection

A first strategy to identifying subtle discriminative features while at the same time preventing overfitting is to combine classical feature selection techniques with randomization, e.g., in the form of random forest classifiers [33.35, 81]. Here, randomization acts as

a regularizer that prevents multiple trees to latch onto the same potentially irrelevant feature, hence reducing the risk of overfitting. Feature selection can also be performed with humans in the loop, using crowd-sourcing and gamification [33.82].

Pose Normalization

A second, orthogonal strategy in fine-grained categorization is to devise factored object class representations that explicitly capture different modes of variation in object appearance, thereby separating variations caused by category membership from variations caused by other factors, such as viewpoint changes. The main idea is to establish a common frame of reference for the extraction of visual features (e.g., a local coordinate system for the dense extraction of SIFT [33.9] features), such that the same object instance will always result in (roughly) the same visual features being extracted, irrespective of viewpoint, lighting, etc.

Specifically, such a frame of reference can be established by first detecting the object of interest in a test image and also localizing its semantic parts. Visual features are then extracted and described relative to the estimated object position and detected parts, ensuring that a feature on the beak of a bird will only ever be compared to a corresponding feature on the beak of another bird, and not on its tail (assuming perfect detection, viewpoint estimation, and part localization). This kind of part-based *pose normalization* has been demonstrated to be effective for bird species categorization [33.83, 84].

Instead of localizing object parts in 2-D, some works establish a common reference frame by estimating a rough 3-D geometry of the object of interest prior to feature extraction, in addition to estimating its viewpoint. This allows not only to describe feature locations relative to the object surface rather than the 2-D image plane (effectively performing the pooling in 3-D [33.36]), but also to rectify image patches with respect to the estimated surface normals, improving the robustness of the resulting feature descriptors with respect to small viewpoint changes. This strategy has proven effective in connection with a prebuilt bird model [33.35] as well as in connection with predicted 3-D CAD model matches for fine-grained car categorization [33.36].

33.2.8 Datasets

Since visual object class recognition approaches rely on machine learning algorithms at their core, they are very much dependent on the availability of sufficient training data – it has in fact been argued that major advances

in the field might have occurred in response of obtaining more data rather than by developing more powerful algorithms [33.85]. At the same time, datasets are of utmost importance in order to quantify and compare the performance of different methods under controlled conditions, and checking the sanity of newly developed algorithms. To that end, benchmark datasets for visual object class recognition typically consist of a collection of images split into training, validation, and test sets, plus a set of ground truth annotations, and often also evaluation scripts that measure the performance of a recognition algorithm relative to the provided annotations.

Since each dataset provides only a small sample of the visual world, there is an inherent danger of being biased [33.85] with respect to which images are selected to be part of a dataset (and which ones are not), and by what means images are captured. As a result, new recognition algorithms should always be tested and cross-trained on multiple datasets in order to prevent overfitting to the characteristics of a particular dataset rather than learning a concept of interest. The following paragraphs give a small, by no means complete, selection of some of today's influential datasets for visual object class recognition.

PASCAL VOC

The PASCAL visual object classes challenge [33.61] stands for a succession of datasets that have been released on a yearly basis from 2005 to 2012. Each dataset consists of multiple challenges (image classification, object class detection, segmentation, human body pose estimation) that are defined on a given set of images. No-

tably, the set of images is steadily increased, such that images of year n are re-used in year $n + 1$. PASCAL VOC counteracts dataset overfitting by not releasing test set ground truth annotations to the public, but instead maintaining an evaluation server that runs a limited number of automated tests for a particular recognition algorithm. PASCAL VOC images have been equipped with additional annotations, e.g., in the form of aligned 3-D CAD models (3-D-PASCAL [33.86]).

SUN and COCO

The scene understanding (SUN) [33.87] and common objects in context (COCO) [33.88] datasets have been built in an effort to capture entire visual scenes rather than objects in isolation. They are meant as benchmarks for methods that reason jointly about multiple objects in a scene rather than performing independent classification or detection.

ImageNet

ImageNet [33.33] is one of the largest image datasets to date, consisting of over 14 million internet images that have been annotated with object labels from the WordNet [33.89] hierarchy. Like PASCAL VOC, it constitutes the basis for multiple challenges that are defined on the dataset, ranging from classification (1000 classes) over object class detection to fine-grained categorization. Due to its massive size, the collection of the ImageNet dataset has been performed mostly by means of crowd sourcing. ImageNet constitutes the basis for pretraining some of the most successful CNN-based image classifiers to date [33.71] (Sect. 33.2.6).

33.3 Discussion and Conclusions

In this chapter, we have discussed visual object class recognition as one of the most fundamental problems in computer vision, with a focus on presenting the most promising models available to practitioners today. The selection of methods that we have reviewed is by no means complete – in favor of going into some depth for the most common techniques, we have skipped over object representations based on manifold learning [33.90] as well as representations based on grammars [33.91, 92], to mention just a few.

As we have seen, practically all available models are inherently based on some notion of object parts that are governed by certain topological constraints. Naturally, the choice of which part-based model to pick is not an easy one, as it depends on many different factors that should be carefully considered.

33.3.1 Task

First of all, the appropriate choice of model is dependent on the application scenario and the resulting desired recognition output: different methods can generate outputs of different granularity, ranging from image-level class labels (basic bag-of-words, Sect. 33.2.1, spatial pyramid matching, Sect. 33.2.2) over 2-D bounding box locations (bag-of-words and spatial pyramid matching run in sliding window fashion, histogram of oriented gradient detectors, Sect. 33.2.4, flexible part models, Sect. 33.2.3, basic deformable part models, Sect. 33.2.5) to multiview detections and viewpoint estimates (multiview ISM, Sect. 33.2.3, 3-D DPM, Sect. 33.2.5).

Secondly, an application scenario typically comes with a certain set of object classes of interest, which

are in turn characterized by rather different visual properties. Rigid objects (like cars or mugs) tend to be handled well by rigid templates (like histogram of oriented gradients, Sect. 33.2.4) or deformable part models (Sect. 33.2.5), while articulate objects (like cats and dogs) can be more reliably represented using looser spatial models like bag of words (Sect. 33.2.1), or by explicitly modeling their kinematic tree structure (pictorial structures, Sect. 33.2.3).

Finally, it should be noted that the distinction between object classes itself is quite arbitrary when drawing strict borders between any two classes. In reality, some classes are inherently more similar than others (e.g., dogs and horses are more similar than dogs and cars, since dogs and horses are both quadrupeds). Looking at multiple levels of object categorization rather than individual classes, it becomes a desired property that objects from the same super-ordinate category, such as quadrupeds, be classified as more similar than objects from different super-ordinate categories. In other words, an object categorization system should degrade gracefully: if the object itself is not correctly recognized, then we want it to be assigned at least to a *similar* category. We thus need a way of representing

the relationship and grading similarities between object categories [33.93].

33.3.2 Data

A particular choice of model implies a certain amount of parameters that have to be learned and additional latent parameters that have to be inferred at test time. A model has to be chosen not only appropriate for the task (above) but also in accordance with the available data at hand in order to prevent over or under fitting.

33.3.3 Efficiency

While simple *feedforward* models like histograms of oriented gradients (Sect. 33.2.4) and bag-of-words (Sect. 33.2.1) are very efficient, modeling deformations and interdependence of parts (flexible part models, Sect. 33.2.3, deformable part models, Sect. 33.2.5) comes at the cost of inferring latent quantities in the model. Notably, this inference often has to be performed repeatedly during learning, underlining the importance of efficient inference procedures.

34. Visual Servoing

François Chaumette, Seth Hutchinson, Peter Corke

This chapter introduces visual servo control, using computer vision data in the servo loop to control the motion of a robot. We first describe the basic techniques that are by now well established in the field. We give a general overview of the formulation of the visual servo control problem, and describe the two archetypal visual servo control schemes: image-based and pose-based visual servo control. We then discuss performance and stability issues that pertain to these two schemes, motivating advanced techniques. Of the many advanced techniques that have been developed, we discuss two-and-a-half-dimensional (2.5-D), hybrid, partitioned, and switched approaches. Having covered a variety of control schemes, we deal with target tracking and controlling motion directly in the joint space and extensions to under-actuated ground and aerial robots. We conclude by describing applications of visual servoing in robotics.

Visual servo (VS) control refers to the use of computer vision data to control the motion of a robot. The vision data may be acquired from a camera that is mounted directly on a robot manipulator or on a mobile robot, in

which case motion of the robot induces camera motion, or the camera can be fixed in the workspace so that it can observe the robot motion from a stationary configuration. Other configurations can be considered, such as

for instance several cameras mounted on pan–tilt heads observing the robot motion. The mathematical development of all these cases is similar, and in this chapter we will focus primarily on the former, so-called *eye-in-hand*, case.

Visual servo control relies on techniques from image processing, computer vision, and control theory. In the present chapter, we will deal primarily with the issues from control theory, making connections to previous chapters when appropriate.

34.1 The Basic Components of Visual Servoing

The aim of all vision-based control schemes is to minimize an error $e(t)$, which is typically defined by

$$e(t) = s(m(t), a) - s^* . \quad (34.1)$$

This formulation is quite general, and it encompasses a wide variety of approaches, as we will see below. The parameters in (34.1) are defined as follows. The vector $m(t)$ is a set of image measurements (e.g., the image coordinates of interest points, or the parameters of a set of image lines or segments). These image measurements are used to compute a vector of k visual features, $s(m(t), a)$, in which a is a set of parameters that represent potential additional knowledge about the system (e.g., true or approximate camera intrinsic parameters or a model of the object to be tracked). The vector s^* contains the desired values of the features. Note that the order of the desired and actual values in (34.1) is reversed with respect to the common convention for feedback control systems.

For now, we consider the case of a fixed goal pose and a motionless target, i. e., s^* is constant, and changes in s depend only on camera motion. Further, we consider here the case of controlling the motion of a camera with six degrees of freedom (e.g., a camera attached to the end effector of a six-degree-of-freedom arm). We will treat more general cases in later sections.

Visual servoing schemes mainly differ in the way that s is designed. In Sects. 34.2 and 34.3, we describe classical approaches, including image-based visual servo control (IBVS), in which s consists of a set of features that are immediately available in the image, and pose-based visual servo control (PBVS), in which s consists of a pose, which must be estimated from image measurements. Note that in the older visual servoing literature PBVS is named position-based, rather than pose-based, visual servoing [34.1, 2]. We also present in Sect. 34.4 several more-advanced methods.

Once s is selected, the design of the control scheme can be quite simple. Perhaps the most straightforward approach is to design a velocity controller. To do this, we require the relationship between the time variation of s and the camera velocity. Let the spatial velocity of the camera be denoted by $v_c = (v_c, \omega_c)$ where v_c is the

instantaneous linear velocity of the origin of the camera frame and ω_c is the instantaneous angular velocity of the camera frame. The relationship between \dot{s} and v_c is given by

$$\dot{s} = L_s v_c , \quad (34.2)$$

in which $L_s \in \mathbb{R}^{k \times 6}$ is called the *interaction matrix* related to s [34.3]. The term *feature Jacobian* is also used somewhat interchangeably in the visual servo literature [34.2], but in the present chapter we will use this latter term to relate the time variation of the features to the robot's joint velocity (Sect. 34.8).

Using (34.1) and (34.2) we immediately obtain the relationship between camera velocity and the time variation of the error

$$\dot{e} = L_e v_c , \quad (34.3)$$

where $L_e = L_s$. Considering v_c as the input to the robot controller, and if we would like, for instance, to design for an exponential and decoupled decrease of the error (i. e., $\dot{e} = -\lambda e$) then using (34.3) we obtain as controller

$$v_c = -\lambda L_e^+ e , \quad (34.4)$$

where $L_e^+ \in \mathbb{R}^{6 \times k}$ is the Moore–Penrose pseudo-inverse of L_e , that is, $L_e^+ = (L_e^T L_e)^{-1} L_e^T$ when $k \geq 6$ and L_e is of full rank 6. When $k = 6$, if $\det L_e \neq 0$ it is possible to invert L_e , giving the control $v_c = -\lambda L_e^{-1} e$. When $k \leq 6$ and L_e is of full rank k , L_e^+ is given by

$$L_e^+ = L_e^T (L_e L_e^T)^{-1} .$$

When L_e is not full rank, the numerical value of L_e^+ can be obtained from the singular value decomposition of L_e . In all cases, control scheme (34.4) allows $\|\dot{e} - \lambda L_e L_e^+ e\|$ and $\|v_c\|$ to be minimal. Note that the desired behavior $\dot{e} = -\lambda e$ is obtained only when $L_e L_e^+ = I_k$, where I_k is the $k \times k$ identity matrix, that is, only when L_e is of full rank k , $k \leq 6$.

In real visual servo systems, it is impossible to know perfectly in practice either L_e or L_e^+ . So an approximation or an estimation of one of these two matrices must

be realized. In the sequel, we denote both the pseudo-inverse of the approximation of the interaction matrix and the approximation of the pseudo-inverse of the interaction matrix by the symbol $\widehat{\mathbf{L}_e^+}$. Using this notation, the control law is in fact

$$\mathbf{v}_c = -\lambda \widehat{\mathbf{L}_e^+} \mathbf{e} = -\lambda \widehat{\mathbf{L}_s^+} (\mathbf{s} - \mathbf{s}^*). \quad (34.5)$$

Closing the loop and assuming that the robot controller is able to realize perfectly \mathbf{v}_c , that is inserting (34.5) into (34.3), we obtain

$$\dot{\mathbf{e}} = -\lambda \mathbf{L}_e \widehat{\mathbf{L}_e^+} \mathbf{e}. \quad (34.6)$$

This equation characterizes the actual behavior of the closed-loop system, which is different from the de-

sired one ($\dot{\mathbf{e}} = -\lambda \mathbf{e}$) when ever

$$\mathbf{L}_e \widehat{\mathbf{L}_e^+} \neq \mathbf{I}_k.$$

It is also the basis of the stability analysis of the system using Lyapunov theory.

What we have presented above is the basic design implemented by most visual servo controllers. All that remains is to fill in the details. How should \mathbf{s} be chosen? What then is the form of \mathbf{L}_s ? How should we estimate $\widehat{\mathbf{L}_e^+}$? What are the performance characteristics of the resulting closed-loop system? These questions are addressed in the remainder of the chapter. We first describe the two basic approaches, **IBVS** and **PBVS**, whose principles were proposed more than 20 years ago [34.1]. We then present more-recent approaches that have improved their performance.

34.2 Image-Based Visual Servo

Traditional image-based control schemes [34.1, 4] use the image-plane normalised coordinates of a set of points to define the vector \mathbf{s} . The image measurements \mathbf{m} are usually the pixel coordinates of the set of image points (although this is not the only possible choice), and the parameters \mathbf{a} in the definition of $\mathbf{s} = \mathbf{s}(\mathbf{m}, \mathbf{a})$ in (34.1) are nothing but the camera intrinsic parameters to go from image measurements expressed in pixels to the features.

34.2.1 The Interaction Matrix

A three-dimensional world point with coordinates $\mathbf{X} = (X, Y, Z)$ in the camera frame projects into the image plane of a conventional perspective camera as a two-dimensional point with normalised coordinates $\mathbf{x} = (x, y)$. More precisely we have

$$\begin{cases} x = \frac{X}{Z} = \frac{u - c_u}{f\alpha} \\ y = \frac{Y}{Z} = \frac{v - c_v}{f} \end{cases}, \quad (34.7)$$

where $\mathbf{m} = (u, v)$ gives the coordinates of the image point expressed in pixel units, and $\mathbf{a} = (c_u, c_v, f, \alpha)$ is the set of camera intrinsic parameters as defined in Chap. 32: c_u and c_v are the coordinates of the principal point, f is the focal length, and α is the ratio of the pixel dimensions. The intrinsic parameter β defined in Chap. 32 has been assumed to be 0 here. In this case, we take $\mathbf{s} = \mathbf{x} = (x, y)$, the image plane coordinates of the point. The details of the imaging geometry

and perspective projection can be found in many computer vision texts, including [34.5–7].

Taking the time derivative of the projection equations (34.7), we obtain

$$\begin{cases} \dot{x} = \frac{\dot{X}}{Z} - \frac{X\dot{Z}}{Z^2} = \frac{\dot{X} - x\dot{Z}}{Z} \\ \dot{y} = \frac{\dot{Y}}{Z} - \frac{Y\dot{Z}}{Z^2} = \frac{\dot{Y} - y\dot{Z}}{Z} \end{cases}. \quad (34.8)$$

We can relate the velocity of the 3-D point to the camera spatial velocity using the well-known equation

$$\dot{\mathbf{X}} = -\mathbf{v}_c - \boldsymbol{\omega}_c \times \mathbf{X} \Leftrightarrow \begin{cases} \dot{X} = -v_x - \omega_y Z + \omega_z Y \\ \dot{Y} = -v_y - \omega_z X + \omega_x Z \\ \dot{Z} = -v_z - \omega_x Y + \omega_y X \end{cases}, \quad (34.9)$$

where $\mathbf{v}_c = (v_x, v_y, v_z)$ and $\boldsymbol{\omega}_c = (\omega_x, \omega_y, \omega_z)$. Inserting (34.9) into (34.8), grouping terms, and using (34.7) we obtain

$$\begin{cases} \dot{x} = \frac{-v_x}{Z} + \frac{xv_z}{Z} + xy\omega_x - (1+x^2)\omega_y + y\omega_z \\ \dot{y} = \frac{-v_y}{Z} + \frac{yv_z}{Z} + (1+y^2)\omega_x - xy\omega_y - x\omega_z \end{cases}, \quad (34.10)$$

which can be written

$$\dot{\mathbf{x}} = \mathbf{L}_x \mathbf{v}_c, \quad (34.11)$$

where the interaction matrix \mathbf{L}_x is given by

$$\mathbf{L}_x = \begin{pmatrix} -\frac{1}{Z} & 0 & \frac{x}{Z} & xy & -(1+x^2) & y \\ 0 & -\frac{1}{Z} & \frac{y}{Z} & 1+y^2 & -xy & -x \end{pmatrix}. \quad (34.12)$$

In the matrix \mathbf{L}_x , the value Z is the depth of the point relative to the camera frame. Therefore, any control scheme that uses this form of the interaction matrix must estimate or approximate the value of Z . Similarly, the camera intrinsic parameters are involved in the computation of x and y . Thus \mathbf{L}_x^+ cannot be *directly* used in (34.4), and an estimation or an approximation $\widehat{\mathbf{L}}_x^+$ must be used, as in (34.5). We discuss this in more detail below.

To control the six degrees of freedom, at least three points are necessary (i.e., we require $k \geq 6$). If we use the feature vector $\mathbf{x} = (x_1, x_2, x_3)$, by merely stacking interaction matrices for three points we obtain

$$\mathbf{L}_x = \begin{pmatrix} \mathbf{L}_{x_1} \\ \mathbf{L}_{x_2} \\ \mathbf{L}_{x_3} \end{pmatrix}.$$

In this case, there will exist some configurations for which \mathbf{L}_x is singular [34.8]. Furthermore, there exist four distinct camera poses for which $\mathbf{e} = \mathbf{0}$, i.e., four global minima exist for the error function $\|\mathbf{e}\|$, and it is impossible to differentiate them [34.9]. For these reasons, more than three points are usually considered.

34.2.2 Approximating the Interaction Matrix

There are several choices available for constructing the estimate $\widehat{\mathbf{L}}_e^+$ to be used in the control law. One popular scheme is of course to choose

$$\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$$

if $\mathbf{L}_e = \mathbf{L}_x$ is known, that is if the current depth Z of each point is available [34.2]. In practice, these parameters must be estimated at each iteration of the control scheme. The basic **IBVS** methods use classical pose-estimation methods (Chap. 32 and the beginning of Sect. 34.3). Another popular approach is to choose

$$\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$$

where \mathbf{L}_{e^*} is the value of \mathbf{L}_e for the desired position $\mathbf{e} = \mathbf{e}^* = \mathbf{0}$ [34.3]. In this case, $\widehat{\mathbf{L}}_e^+$ is constant, and only the desired depth of each point has to be set, which means no varying 3-D parameters have to be estimated during the visual servo. Finally, the choice

$$\widehat{\mathbf{L}}_e^+ = \left(\frac{\mathbf{L}_e}{2} + \frac{\mathbf{L}_{e^*}}{2} \right)^+$$

has been proposed [34.10]. Since \mathbf{L}_e is involved in this method, the current depth of each point also has to be available.

We illustrate the behavior of these control schemes with an example. The goal is to position the camera so that it observes a square centered in the image (Fig. 34.1). We define s to include the x and y coordinates of the four points forming the square. Note

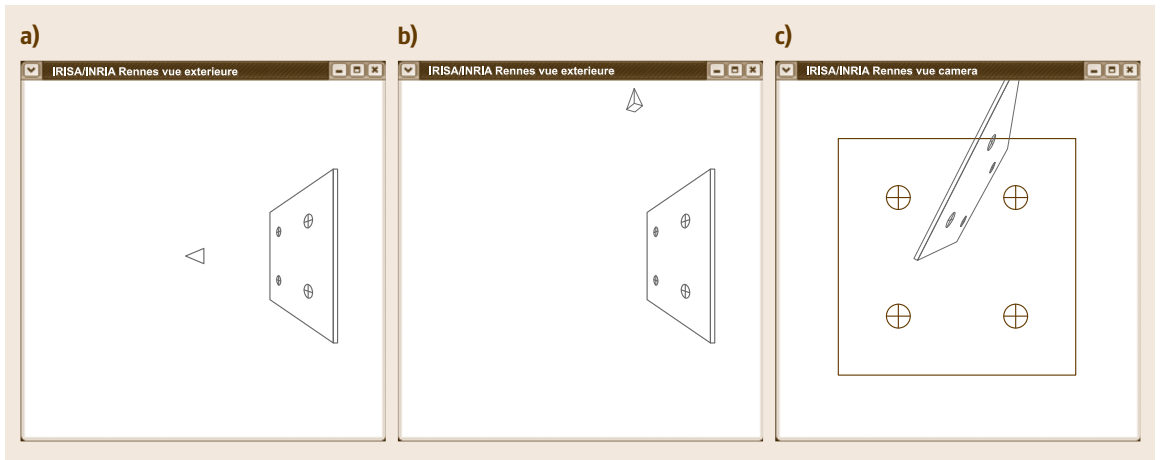

Fig.34.1a–c Example of positioning task: (a) the desired camera pose with respect to a simple target, (b) the initial camera pose, and (c) the corresponding initial and desired image of the target

Fig.34.2a-c IBVS system behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$: (a) image point trajectories including the trajectory of the center of the square, which is not used in the control scheme, (b) v_c components (cm/s and deg/s) computed at each iteration of the control scheme, and (c) the 3-D trajectory of the camera optical center expressed in the desired camera frame \mathcal{R}_{c^*} (cm)

Fig.34.3a-c IBVS system behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$ (refer to Fig. 34.2a-c for description)

that the initial camera pose has been selected far away from the desired pose, particularly with regard to the rotational motions, which are known to be the most problematic for IBVS. In the simulations presented in the following, no noise or modeling errors have been introduced in order to allow comparison of different behaviors in perfect conditions. The accompanying videos show experimental results obtained using an Adept Viper robot arm and the ViSP library [34.11]. The videos all show the same task being performed from the same initial conditions, and only the control approach varies.

The results obtained by using

$$\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+$$

are given in Fig. 34.2 and VIDEO 59. Note that despite the large displacement that is required the system converges. However, neither the behavior in the image, nor the computed camera velocity components, nor the 3-D trajectory of the camera present desirable properties far from the convergence (i. e., for the first 30 or so iterations).

The results obtained using

$$\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$$

are given in Fig. 34.3 and VIDEO 60. In this case, the trajectories of the points in the image are almost straight lines, which means that the points never leave the camera's field of view. However the behavior induced in the camera frame is even less satisfactory than for the case of

$$\widehat{\mathbf{L}}_e^+ = \mathbf{L}_{e^*}^+.$$

The large camera velocities at the beginning of the servo indicate that the condition number of $\widehat{\mathbf{L}}_e^+$ is high at the start of the trajectory, and the camera trajectory is far from a straight line.

The choice

$$\widehat{\mathbf{L}}_e^+ = \left(\frac{\mathbf{L}_e}{2} + \frac{\mathbf{L}_{e^*}}{2} \right)^+$$

provides good performance in practice. Indeed, as can be seen in Fig. 34.4, the camera velocity components do not include large oscillations, which provides

Fig. 34.4 IBVS system behavior using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = (\mathbf{L}_e/2 + \mathbf{L}_e^*/2)^+$ (refer to Fig. 34.2a-c for description)

a smooth trajectory in both the image and in 3-D space (VIDEO 61).

34.2.3 A Geometrical Interpretation of IBVS

It is quite easy to provide a geometric interpretation of the behavior of the control schemes defined above. The example illustrated in Fig. 34.5 corresponds to a pure rotation around the optical axis from the initial configuration (shown in blue) to the desired configuration of four coplanar points parallel to the image plane (shown in red).

As explained above, using \mathbf{L}_e^+ in the control scheme attempts to ensure an exponential decrease of the er-

ror e . This means that, when x and y image point coordinates compose this error, the points' trajectories in the image follow straight lines from their initial to their desired positions, when this is possible. This leads to the image motion plotted in green in the figure. The camera motion to realize this image motion can be easily deduced and is indeed composed of a rotational motion around the optical axis, but combined with a retreating translational motion along the optical axis [34.12]. This unexpected motion is due to the choice of the features and the form of the third and sixth columns in the interaction matrix, which induces a coupling between the features and the two degrees of freedom involved (v_z and ω_z). If the rotation between the initial and desired configurations is very large, this phenomenon is amplified, and leads to a particular case for a rotation of π radians where no rotational motion at all will be induced by the control scheme [34.13]. On the other hand, when the rotation is small, this phenomenon almost disappears. To conclude, the behavior is locally satisfactory (i. e., when the error is small), but it can be unsatisfactory when the error is large. As we will see below, these results are consistent with the local asymptotic stability results that can be obtained for IBVS.

If instead we use $\mathbf{L}_{e^*}^+$ in the control scheme, the image motion generated can easily be shown to be the blue one plotted in Fig. 34.5. Indeed, if we consider the same control scheme as before but starting from s^* to reach s , we obtain

$$\mathbf{v}_c = -\lambda \mathbf{L}_{e^*}^+ (s^* - s),$$

which again induces straight-line trajectories from the red points to the blue ones, causing the image motion plotted in brown. Going back to our problem, the control scheme computes a camera velocity that is exactly the opposite one

$$\mathbf{v}_c = -\lambda \mathbf{L}_{e^*}^+ (s - s^*),$$

Fig. 34.5 Geometrical interpretation of IBVS: going from the blue position to the red one. In green, image motion when \mathbf{L}_e^+ is used in the control scheme; in blue, when $\mathbf{L}_{e^*}^+$ is used; and in black when $(\mathbf{L}_e/2 + \mathbf{L}_{e^*}/2)^+$ is used (see the text for more details)

and thus generates the image motion plotted in red at the red points. Transformed to the blue points, the camera velocity generates the blue image motion and corresponds once again to a rotational motion around the optical axis, combined now with an unexpected forward motion along the optical axis. The same analysis can be done as before for the case of large or small errors. We can add that, as soon as the error decreases significantly, both control schemes get closer, and tend to the same one (since $\mathbf{L}_e = \mathbf{L}_{e^*}$ when $e = e^*$) with a nice behavior characterized with the image motion plotted in black and a camera motion composed of only a rotation around the optical axis when the error tends towards zero.

If we instead use

$$\widehat{\mathbf{L}}_e^+ = \left(\frac{\mathbf{L}_e}{2} + \frac{\mathbf{L}_{e^*}}{2} \right)^+,$$

it is intuitively clear that considering the mean of \mathbf{L}_e and \mathbf{L}_{e^*} generates the image motion plotted in black, even when the error is large. In all cases but the rotation of π radians, the camera motion is now a pure rotation around the optical axis, without any unexpected translational motion.

34.2.4 Stability Analysis

We now consider the fundamental issues related to the stability of IBVS. To assess the stability of the closed-loop visual servo systems, we will use Lyapunov analysis. In particular, consider the candidate Lyapunov function defined by the squared error norm $\mathcal{L} = \frac{1}{2} \|e(t)\|^2$, whose derivative is given by

$$\dot{\mathcal{L}} = e^T \dot{e} = -\lambda e^T \widehat{\mathbf{L}}_e^+ e$$

since \dot{e} is given by (34.6). The global asymptotic stability of the system is thus obtained when the following sufficient condition is satisfied

$$\mathbf{L}_e \widehat{\mathbf{L}}_e^+ > 0. \quad (34.13)$$

If the number of features is equal to the number of camera degrees of freedom (i. e., $k = 6$), and if the features are chosen and the control scheme designed so that \mathbf{L}_e and $\widehat{\mathbf{L}}_e^+$ are of full rank 6, then the condition (34.13) is satisfied if the approximations involved in $\widehat{\mathbf{L}}_e^+$ are not too coarse.

As discussed above, for most IBVS approaches we have $k > 6$. Therefore the condition (34.13) can never be ensured since

$$\mathbf{L}_e \widehat{\mathbf{L}}_e^+ \in \mathbb{R}^{k \times k}$$

is at most of rank 6, and thus $\mathbf{L}_e \widehat{\mathbf{L}}_e^+$ has a nontrivial null space. In this case, configurations such that $e \in \ker \widehat{\mathbf{L}}_e^+$ correspond to local minima. Reaching such a local minimum is illustrated in Fig. 34.6. As can be seen in Fig. 34.6d, each component of e has a nice exponential decrease with the same convergence speed, causing straight-line trajectories to be realized in the image, but the error reached is not exactly zero, and it is clear from Fig. 34.6c that the system has been attracted to a local minimum far away from the desired configuration. Thus, only local asymptotic stability can be obtained for IBVS.

To study local asymptotic stability when $k > 6$, let us first define a new error e' with $e' = \widehat{\mathbf{L}}_e^+ e$. The time derivative of this error is given by

$$\dot{e}' = \widehat{\mathbf{L}}_e^+ \dot{e} + \dot{\widehat{\mathbf{L}}_e^+} e = \left(\widehat{\mathbf{L}}_e^+ \mathbf{L}_e + \mathbf{O} \right) v_c,$$

where $\mathbf{O} \in \mathbb{R}^{6 \times 6}$ is equal to $\mathbf{0}$ when $e = 0$, whatever the choice of $\widehat{\mathbf{L}}_e^+$ [34.14]. Using the control scheme (34.5), we obtain

$$\dot{e}' = -\lambda \left(\widehat{\mathbf{L}}_e^+ \mathbf{L}_e + \mathbf{O} \right) e',$$

which is known to be locally asymptotically stable in a neighborhood of $e = e^* = \mathbf{0}$ if

$$\widehat{\mathbf{L}}_e^+ \mathbf{L}_e > 0, \quad (34.14)$$

where $\widehat{\mathbf{L}}_e^+ \mathbf{L}_e \in \mathbb{R}^{6 \times 6}$. Indeed, only the linearized system

$$\dot{e}' = -\lambda \widehat{\mathbf{L}}_e^+ \mathbf{L}_e e'$$

has to be considered if we are interested in the local asymptotic stability [34.15].

Once again, if the features are chosen and the control scheme designed so that \mathbf{L}_e and $\widehat{\mathbf{L}}_e^+$ are of full rank 6, then condition (34.14) is ensured if the approximations involved in $\widehat{\mathbf{L}}_e^+$ are not too coarse.

To end the demonstration of local asymptotic stability, we must show that there does not exist any configuration $e \neq e^*$ such that $e \in \ker \widehat{\mathbf{L}}_e^+$ in a small neighborhood of e^* and in a small neighborhood of the corresponding pose p^* . Such configurations correspond to local minima where $v_c = 0$ and $e \neq e^*$. If such a pose p would exist, it is possible to restrict the neighborhood around p^* so that there exists a camera velocity v to reach p^* from p . This camera velocity would imply a variation of the error $\dot{e} = \mathbf{L}_e v$. However, such a variation cannot belong to $\ker \widehat{\mathbf{L}}_e^+$ since $\widehat{\mathbf{L}}_e^+ \mathbf{L}_e > 0$. Therefore, we have $v_c = 0$ if and only if $\dot{e} = \mathbf{0}$, i. e., $e = e^*$, in a neighborhood of p^* .

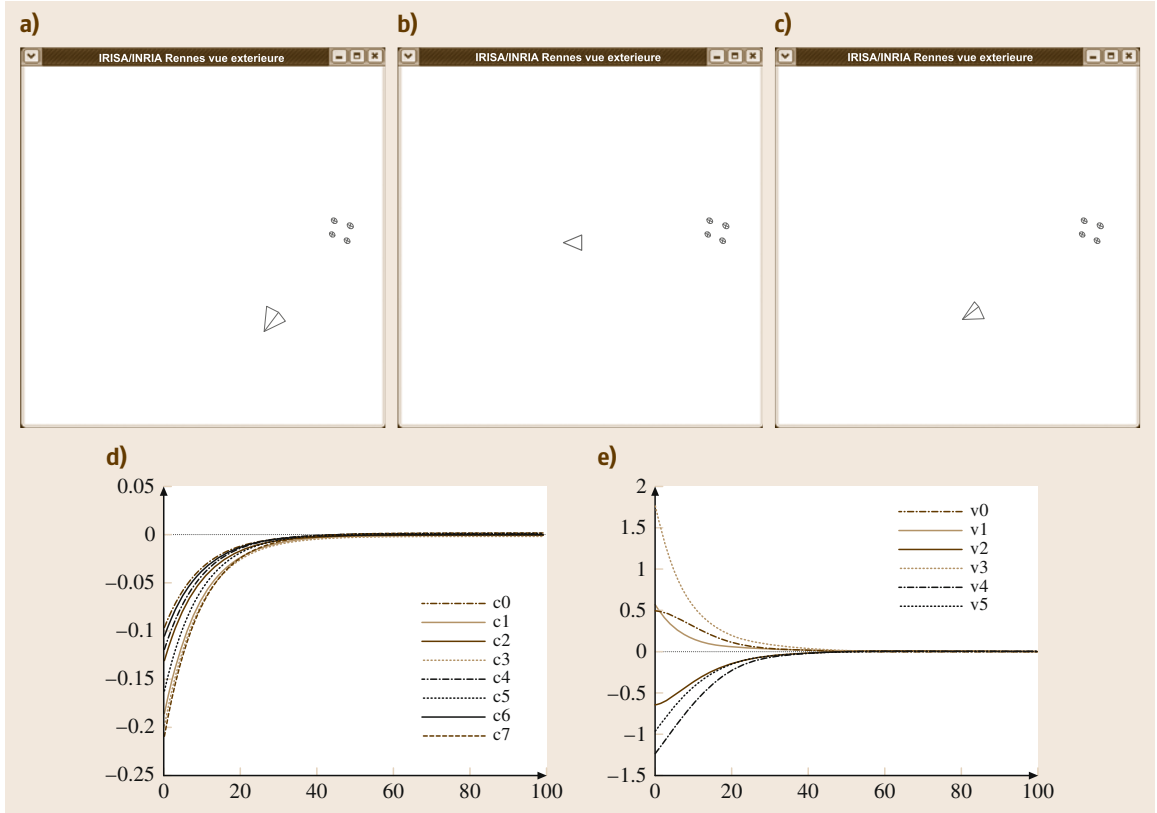

Fig.34.6a–e IBVS reaching a local minimum using $s = (x_1, y_1, \dots, x_4, y_4)$ and $\widehat{\mathbf{L}}_e^+ = \mathbf{L}_e^+$: (a) the initial configuration, (b) the desired one, (c) the configuration reached after the convergence of the control scheme, (d) the evolution of the error e at each iteration of the control scheme, and (e) the evolution of the six components of the camera velocity v_c

Even though local asymptotic stability can be ensured when $k > 6$, we recall that global asymptotic stability cannot be ensured. For instance, as illustrated in Fig. 34.6, there may exist local minima corresponding to configurations where $e \in \ker \widehat{\mathbf{L}}_e^+$, which are outside of the neighborhood considered above. Determining the size of the neighborhood in which stability and the convergence are ensured is still an open issue, even if this neighborhood is surprisingly quite large in practice.

34.2.5 IBVS with a Stereo Vision System

It is straightforward to extend the IBVS approach to a multicamera system. If a stereo vision system is used, and a world point is visible in both left and right images (Fig. 34.7), it is possible to use as visual features

$$s = \mathbf{x}_s = (x_l, \mathbf{x}_r) = (x_l, y_l, x_r, y_r)$$

i. e., to represent the point by just stacking in s the x and y coordinates of the observed point in the left and right

images [34.16]. However, care must be taken when constructing the corresponding interaction matrix since the form given in (34.11) is expressed in either the left or right camera frame. More precisely, we have

$$\begin{cases} \dot{x}_l &= \mathbf{L}_{x_l} v_l, \\ \dot{x}_r &= \mathbf{L}_{x_r} v_r, \end{cases}$$

where v_l and v_r are the spatial velocity of the left and right camera, respectively, and where the analytical form of \mathbf{L}_{x_l} and \mathbf{L}_{x_r} are given by (34.12).

By choosing a sensor frame rigidly linked to the stereo vision system, we obtain

$$\dot{\mathbf{x}}_s = \begin{pmatrix} \dot{x}_l \\ \dot{x}_r \end{pmatrix} = \mathbf{L}_{x_s} v_s,$$

where the interaction matrix related to \mathbf{x}_s can be determined using the spatial motion transform matrix \mathbf{V} defined in Chap. 02 to transform velocities expressed in the left or right cameras frames to the sensor frame. We

recall that \mathbf{V} is given by

$$\mathbf{V} = \begin{pmatrix} \mathbf{R} & [\mathbf{t}]_{\times} \mathbf{R} \\ \mathbf{0} & \mathbf{R} \end{pmatrix}, \quad (34.15)$$

where $[\mathbf{t}]_{\times}$ is the skew-symmetric matrix associated to the vector \mathbf{t} and where $(\mathbf{R}, \mathbf{t}) \in SE(3)$ is the rigid-body transformation from the camera to the sensor frame. The numerical values for these matrices are directly obtained from the calibration step of the stereo vision system. Using this equation, we obtain

$$\mathbf{L}_{x_s} = \begin{pmatrix} \mathbf{L}_{x_l}^T \mathbf{V}_s \\ \mathbf{L}_{x_r}^T \mathbf{V}_s \end{pmatrix}.$$

Note that $\mathbf{L}_{x_s} \in \mathbb{R}^{4 \times 6}$ is always of rank 3 because of the epipolar constraint that links the perspective projection of a 3-D point in a stereo vision system (Fig. 34.7). Another simple interpretation is that a 3-D point is represented by three independent parameters, which makes it impossible to find more than three independent parameters using any sensor observing that point.

To control the six degrees of freedom of the system, it is necessary to consider at least three points, as the rank of the interaction matrix considering only two points is 5.

Using a stereo vision system, since the 3-D coordinates of any point observed in both images can be easily estimated by a simple triangulation process it is possible and quite natural to use these 3-D coordinates in the features set \mathbf{s} . Such an approach would be, strictly speaking, a position-based approach, since it would require 3-D parameters in \mathbf{s} .

34.2.6 IBVS with Cylindrical Coordinates of Image Points

In the previous sections, we have considered the Cartesian coordinates of image points. As proposed in [34.17] it may be useful to consider instead the cylindrical coordinates $\boldsymbol{\gamma} = (\rho, \theta)$ of the image points

Fig. 34.7 A stereo vision system

instead of their Cartesian coordinates $\mathbf{x} = (x, y)$. They are given by

$$\rho = \sqrt{x^2 + y^2}, \quad \theta = \arctan \frac{y}{x}$$

from which we deduce

$$\dot{\rho} = \frac{x\dot{x} + y\dot{y}}{\rho}, \quad \dot{\theta} = \frac{x\dot{y} - y\dot{x}}{\rho^2}.$$

Using (34.11) and then substituting x by $\rho \cos \theta$ and y by $\rho \sin \theta$, we obtain immediately

$$\mathbf{L}_{\boldsymbol{\gamma}} = \begin{pmatrix} \frac{-c}{Z} & \frac{-s}{Z} & \frac{\rho}{Z} & (1 + \rho^2)s & -(1 + \rho^2)c & 0 \\ \frac{s}{\rho Z} & \frac{-c}{\rho Z} & 0 & \frac{c}{\rho} & \frac{s}{\rho} & -1 \end{pmatrix}, \quad (34.16)$$

where $c = \cos \theta$ and $s = \sin \theta$. Note that θ is not defined when the image point lies at the principal point (where $x = y = \rho = 0$). It is thus not surprising that the interaction matrix $\mathbf{L}_{\boldsymbol{\gamma}}$ is singular in that case.

If we go back to the example depicted in Fig. 34.5, the behavior obtained using cylindrical coordinates will be the expected one, that is a pure rotation around the optical axis, by using either \mathbf{L}_e^+ , \mathbf{L}_e^* or $(\mathbf{L}_e/2 + \mathbf{L}_e^*/2)^+$ in the control scheme. This is due to the form of the third and sixth columns of the interaction matrix (34.16), which leads to a decoupled system.

34.2.7 IBVS with Other Geometrical Features

In the previous sections, we have only considered image point coordinates in \mathbf{s} . Other geometrical primitives can of course be used. There are several reasons to do so. Firstly, the scene observed by the camera cannot always be described merely by a collection of points, in which case the image processing provides other types of measurements, such as a set of straight lines or the contours of an object. Secondly, richer geometric primitives may ameliorate the decoupling and linearizing issues that motivate the design of partitioned systems (Sect. 34.4). Finally, the robotic task to be achieved may be expressed in terms of virtual linkages (or fixtures) between the camera and the observed objects [34.18, 19], sometimes expressed directly by constraints between primitives, such as point-to-line [34.20] (which means that an observed point must lie on a specified line).

It is possible to determine the interaction matrix related to the perspective projection of a large class of geometrical primitives, such as segments, straight lines, spheres, circles, and cylinders. The results are given in [34.3, 18]. Recently, the analytical form of the interaction matrix related to any image moments corresponding to planar objects has been computed. This

Fig. 34.8 Unified imaging model of Geyer and Daniilidis (after [34.7])

makes it possible to consider planar objects of any shape [34.21]. If a collection of points is measured in the image, moments can also be used [34.22]. In both cases, moments allow the use of intuitive geometrical features, such as the center of gravity or the orientation of an object. By selecting an adequate combination of moments, it is then possible to determine partitioned systems with good decoupling and linearizing properties [34.21, 22].

Note that, for all these features (geometrical primitives, moments), the depth of the primitive or of the object considered appears in the coefficients of the interaction matrix related to the translational degrees of freedom, as was the case for the image points. An estimation of this depth is thus generally necessary (Sect. 34.6). In a few situations, for instance with a suitable normalization of moments [34.22], only the constant desired depth appears in the interaction matrix, which makes estimating depth unnecessary.

34.2.8 Non-Perspective Cameras

The vast majority of cameras we use, and our own eyes, are characterized by a perspective projection model which closely approximate the ideal pinhole imaging model. Such cameras have a narrow field of view, typically less than one half hemisphere. For robotics it is often advantageous to have a large field of view and this can be achieved using a fisheye lens camera or a catadioptric (lens and mirror system) camera (often referred to as a panoramic camera). For these non-perspective sensors the interaction matrix of any visual feature has a different form to those discussed above, such as (34.12) and (34.16) for an image point.

Rather than determine the interaction matrix of visual features expressed in the image plane of non-perspective cameras, we can transform the images from these cameras to the view that would be seen by an ideal spherical camera. The spherical model projects world points onto a unit sphere, the intersection of the unit sphere with the ray from the world point to the center of the sphere. Such an ideal camera has the largest possible field of view. The unified imaging model [34.23] shown in Fig 34.8b provides a general mechanism to project a world point to the image plane of a large class of cameras. To be precise it includes all central projection cameras and this includes perspective and some catadioptric cameras with particular mirror shapes, but in practice it is a very good approximation to non-central cameras including fisheye and general catadioptric systems. The mechanism of this unified model can also be used to reproject points from these varied image planes to a spherical camera.

Referring to Fig. 34.8 the world point \mathbf{P} is represented by the vector $\mathbf{X} = (X, Y, Z)$ in the camera frame, and is projected onto the surface of the unit sphere at the point $\mathbf{x}_s = (x_s, y_s, z_s)$ with

$$x_s = \frac{X}{R}, \quad y_s = \frac{Y}{R}, \quad \text{and} \quad z_s = \frac{Z}{R},$$

where $R = \sqrt{X^2 + Y^2 + Z^2}$ is the distance from the sphere center to the world point.

The interaction matrix of \mathbf{x}_s is derived in essentially the same manner as for the perspective camera, and it can be shown to be [34.24]

$$\mathbf{L}_{\mathbf{x}_s} = \left[\frac{1}{R} (\mathbf{x}_s \mathbf{x}_s^T - \mathbf{I}_3) [\mathbf{x}_s]_{\times} \right]. \quad (34.17)$$

Note that R can be expressed as a function of the point depth Z by using $R = Z \sqrt{1 + x_s^2 + y_s^2}$. Therefore, the general spherical model does not add any supplementary unknown in the interaction matrix.

A particular advantage of the spherical model is that for pure camera rotation the shape of an object is invariant, which eases determining visual features that are only linked to translational motions.

34.2.9 Direct Estimation

In the previous sections, we have focused on the analytical form of the interaction matrix. It is also possible to estimate its numerical value directly using either an offline learning step, or an online estimation scheme.

All the methods proposed to estimate the interaction matrix numerically rely on the observation of a variation of the features due to a known or measured camera motion. More precisely, if we measure a feature's variation Δs due to a camera motion $\Delta \mathbf{v}_c$, we

have from (34.2)

$$\mathbf{L}_s \Delta \mathbf{v}_c = \Delta \mathbf{s},$$

which provides k equations while we have $k \times 6$ unknown values in \mathbf{L}_s . Using a set of N independent camera motions with $N > 6$, it is thus possible to estimate \mathbf{L}_s by solving

$$\mathbf{L}_s \mathbf{A} = \mathbf{B},$$

where the columns of $\mathbf{A} \in \mathbb{R}^{6 \times N}$ and $\mathbf{B} \in \mathbb{R}^{k \times N}$ are, respectively, formed from the set of camera motions and the set of corresponding features variations. The least-square solution is of course given by

$$\widehat{\mathbf{L}}_s = \mathbf{B} \mathbf{A}^+ . \quad (34.18)$$

Methods based on neural networks have also been developed to estimate \mathbf{L}_s [34.25, 26]. It is also possible to estimate the numerical value of \mathbf{L}_s^+ directly, which in practice provides a better behavior [34.27]. In this case, the basic relation is

$$\mathbf{L}_s^+ \Delta \mathbf{s} = \Delta \mathbf{v}_c ,$$

which provides six equations. Using a set of N measurements, with $N > k$, we now obtain

$$\widehat{\mathbf{L}}_s^+ = \mathbf{A} \mathbf{B}^+ . \quad (34.19)$$

34.3 Pose-Based Visual Servo

Pose-based control schemes (PBVS) [34.1, 32, 33] use the pose of the camera with respect to some reference coordinate frame to define s . Computing this pose from a set of measurements in one image necessitates the camera intrinsic parameters and the 3-D model of the object observed to be known. This classic computer vision problem is called the 3-D localization problem. While this problem is beyond the scope of the present chapter, many solutions have been presented in the literature [34.34, 35] and its basic principles are recalled in Chap. 32.

It is then typical to define s in terms of the parameterization used to represent the camera pose. Note that the parameters \mathbf{a} involved in the definition (34.1) of s are now the camera intrinsic parameters and the 3-D model of the object.

It is convenient to consider three coordinate frames: the current camera frame \mathcal{F}_c , the desired camera frame \mathcal{F}_c^* , and a reference frame \mathcal{F}_o attached to the

In the first case (34.18), the six columns of \mathbf{L}_s are estimated by solving six linear systems, while in the second case (34.19), the k columns of \mathbf{L}_s^+ are estimated by solving k linear systems, which explains the difference in the results.

Estimating the interaction matrix online can be viewed as an optimization problem, and consequently a number of researchers have investigated approaches that derive from optimization methods. These methods typically discretize the system equation (34.2), and use an iterative updating scheme to refine the estimate of $\widehat{\mathbf{L}}_s$ at each stage. One such online and iterative formulation uses the Broyden update rule given by [34.28, 29]

$$\begin{aligned} \widehat{\mathbf{L}}_s(t+1) = & \widehat{\mathbf{L}}_s(t) \\ & + \frac{\alpha}{\Delta \mathbf{v}_c^T \Delta \mathbf{v}_c} \left[\Delta \mathbf{x} - \widehat{\mathbf{L}}_s(t) \Delta \mathbf{v}_c \right] \Delta \mathbf{v}_c^T, \end{aligned}$$

where α defines the update speed. This method has been generalized to the case of moving objects in [34.30].

The main interest of using such numerical estimations in the control scheme is that it avoids all the modeling and calibration steps. It is particularly useful when using features whose interaction matrix is not available in analytical form. For instance, in [34.31], the main eigenvalues of the principal component analysis of an image have been considered in a visual servoing scheme. The drawback of these methods is that no theoretical stability and robustness analysis can be made.

object. We adopt here the standard notation of using a leading superscript to denote the frame with respect to which a set of coordinates is defined. Thus, the coordinate vectors ${}^c \mathbf{t}_o$ and ${}^{c^*} \mathbf{t}_o$ give the coordinates of the origin of the object frame expressed relative to the current camera frame, and relative to the desired camera frame, respectively. Furthermore, let $\mathbf{R} = {}^{c^*} \mathbf{R}_c$ be the rotation matrix that gives the orientation of the current camera frame relative to the desired frame.

We can define s to be $(\mathbf{t}, \theta \mathbf{u})$, in which \mathbf{t} is a translation vector, and $\theta \mathbf{u}$ gives the angle/axis parameterization for the rotation. We now discuss two choices for \mathbf{t} , and give the corresponding control laws.

If \mathbf{t} is defined relative to the object frame \mathcal{F}_o , we obtain

$$s = ({}^c \mathbf{t}_o, \theta \mathbf{u}), s^* = ({}^{c^*} \mathbf{t}_o, 0),$$

and

$$e = ({}^c \mathbf{t}_o - {}^{c^*} \mathbf{t}_o, \theta \mathbf{u}).$$

Fig. 34.9 PBVS system behavior using $s = ({}^c t_0, \theta u)$ (refer to Fig. 34.2a-c for description)

In this case, the interaction matrix related to e is given by

$$\mathbf{L}_e = \begin{pmatrix} -\mathbf{I}_3 & [{}^c t_0]_{\times} \\ \mathbf{0} & \mathbf{L}_{\theta u} \end{pmatrix}, \quad (34.20)$$

in which \mathbf{I}_3 is the 3×3 identity matrix and $\mathbf{L}_{\theta u}$ is given by [34.36]

$$\mathbf{L}_{\theta u} = \mathbf{I}_3 + \frac{\theta}{2} [u]_{\times} + \left(1 - \frac{\text{sinc } \theta}{\text{sinc}^2 \theta/2}\right) [u]_{\times}^2, \quad (34.21)$$

where $\text{sinc } x$ is the sinus cardinal defined such that $x \text{ sinc } x = \sin x$ and $\text{sinc } 0 = 1$.

Following the development in Sect. 34.1, we obtain the control scheme

$$v_c = -\lambda \widehat{\mathbf{L}_e^{-1}} e$$

since the dimension k of s is six, that is, the number of camera degrees of freedom. By setting

$$\widehat{\mathbf{L}_e^{-1}} = \begin{pmatrix} -\mathbf{I}_3 & [{}^c t_0]_{\times} \mathbf{L}_{\theta u}^{-1} \\ \mathbf{0} & \mathbf{L}_{\theta u}^{-1} \end{pmatrix}, \quad (34.22)$$

we obtain after simple developments

$$\begin{cases} v_c = -\lambda [{}^c t_0 - {}^c t_0^*] + [{}^c t_0]_{\times} \theta u \\ \omega_c = -\lambda \theta u \end{cases}. \quad (34.23)$$

since $\mathbf{L}_{\theta u}$ is such that

$$\mathbf{L}_{\theta u}^{-1} \theta u = \theta u.$$

Ideally, that is, if the pose parameters are perfectly estimated, the behavior of e will be the expected one ($\dot{e} = -\lambda e$). The choice of e causes the rotational

motion to follow a geodesic with an exponential decreasing speed and causes the translational parameters involved in s to decrease at the same speed. This explains the nice exponential decrease of the camera velocity components in Fig. 34.9. Furthermore, the trajectory in the image of the origin of the object frame follows a straight line (here the center of the four points has been selected as this origin). On the other hand, the camera trajectory does not follow a straight line (VIDEO 62).

Another PBVS scheme can be designed by using $s = ({}^c t_c, \theta u)$. In this case, we have $s^* = \mathbf{0}$, $e = s$, and

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{R} & \mathbf{0} \\ \mathbf{0} & \mathbf{L}_{\theta u} \end{pmatrix}. \quad (34.24)$$

Note the decoupling between translational and rotational motions, which allows us to obtain a simple control scheme

$$\begin{cases} v_c = -\lambda \mathbf{R}^T {}^c t_c \\ \omega_c = -\lambda \theta u \end{cases}. \quad (34.25)$$

In this case, as can be seen in Fig. 34.10 and in VIDEO 63, if the pose parameters involved in (34.25) are estimated perfectly, the camera trajectory is a straight line, while the image trajectories are less satisfactory than before. Some particular configurations can be found which will lead to some points leaving the camera field of view during the robot motion.

The stability properties of PBVS seem quite attractive. Since $\mathbf{L}_{\theta u}$ given in (34.21) is nonsingular when $\theta \neq 2k\pi$, $\forall k \in \mathbb{Z}^*$, we obtain from (34.13) the global asymptotic stability of the system since $\mathbf{L}_e \widehat{\mathbf{L}_e^{-1}} = \mathbf{I}_6$, under the strong hypothesis that all the pose parameters are perfect. This is true for both methods presented above, since the interaction matrices given in (34.20) and (34.24) are full rank when $\mathbf{L}_{\theta u}$ is nonsingular.

Fig. 34.10 PBVS system behavior using $s = ({}^c t_c, \theta u)$ (refer to Fig. 34.2a-c for description)

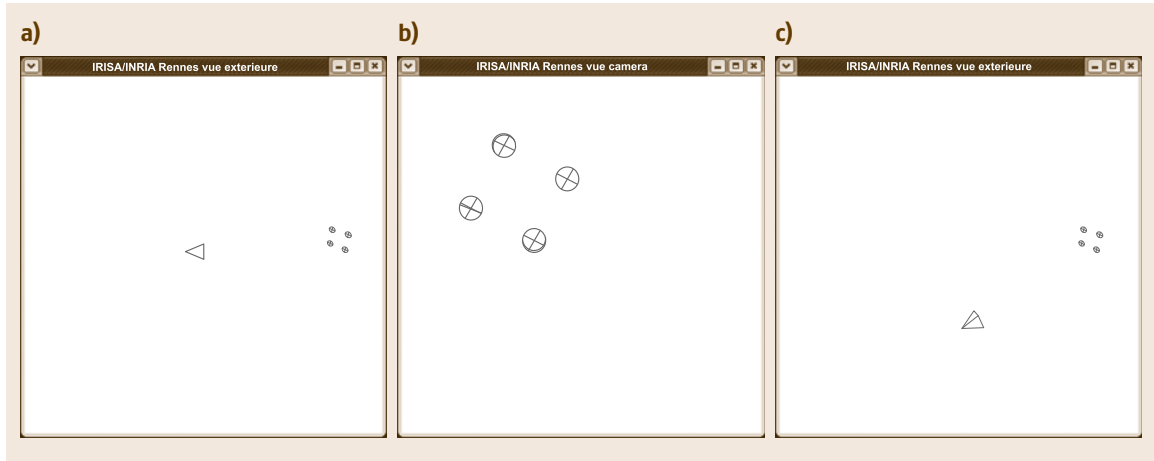

Fig. 34.11a–c Two different camera poses (a,c) that provide almost the same image of four coplanar points shown overlaid in (b)

With regard to robustness, feedback is computed using *estimated* quantities that are a function of the image measurements and the system calibration parameters. For the first method presented in Sect. 34.3 (the analysis for the second method is analogous), the interaction matrix given in (34.20) corresponds to perfectly estimated pose parameters, while the real one is unknown since the estimated pose parameters may be biased due to calibration errors, or inaccurate and unstable due to noise [34.13]. The true positivity condition (34.13)

should in fact be written

$$\mathbf{L}_{\hat{e}} \widehat{\mathbf{L}_{\hat{e}}}^{-1} > 0, \quad (34.26)$$

where $\widehat{\mathbf{L}_{\hat{e}}}^{-1}$ is given by (34.22) but where $\mathbf{L}_{\hat{e}}$ is unknown, and not given by (34.20). Indeed, even small errors in computing the position of points in the image can lead to pose errors which will significantly impact the accuracy and the stability of the system (Fig. 34.11).

34.4 Advanced Approaches

34.4.1 Hybrid VS

Suppose we have access to a control law for ω_c , such as the one used in PBVS ((34.23) or (34.25))

$$\omega_c = -\lambda \theta u. \quad (34.27)$$

How could we use this in conjunction with IBVS?

Considering a feature vector s_t and an error e_t devoted to control the translational degrees of freedom, we can partition the interaction matrix as follows

$$\begin{aligned} \dot{s}_t &= \mathbf{L}_{s_t} v_c \\ &= (\mathbf{L}_v \ \mathbf{L}_\omega) \begin{pmatrix} v_c \\ \omega_c \end{pmatrix} \\ &= \mathbf{L}_v v_c + \mathbf{L}_\omega \omega_c. \end{aligned}$$

Now, setting $\dot{e}_t = -\lambda e_t$, we can solve for the desired translational control input as

$$\begin{aligned} -\lambda e_t &= \dot{e}_t = \dot{s}_t = \mathbf{L}_v v_c + \mathbf{L}_\omega \omega_c, \\ \Rightarrow v_c &= -\mathbf{L}_v^+ (\lambda e_t + \mathbf{L}_\omega \omega_c). \end{aligned} \quad (34.28)$$

We can think of the quantity $(\lambda e_t + \mathbf{L}_\omega \omega_c)$ as a modified error term, one that combines the original error with the error that would be induced by the rotational motion due to ω_c . The translational control input $v_c = -\mathbf{L}_v^+ (\lambda e_t + \mathbf{L}_\omega \omega_c)$ will drive this error to zero. The method known as 2.5-D visual servo [34.36] was the first to exploit such a partitioning in combining IBVS and PBVS. More precisely, in [34.36], s_t has been selected as the coordinates of an image point, and the logarithm of its depth, so that \mathbf{L}_v is a triangular always invertible matrix. More precisely, we have $s_t = (x, \log Z)$, $s_t^* = (x^*, \log Z^*)$, $e_t = (x - x^*, \log \rho_Z)$ where $\rho_Z = Z/Z^*$, and

$$\begin{aligned} \mathbf{L}_v &= \frac{1}{Z^* \rho_Z} \begin{pmatrix} -1 & 0 & x \\ 0 & -1 & y \\ 0 & 0 & -1 \end{pmatrix} \mathbf{L}_\omega \\ &= \begin{pmatrix} xy & -(1+x^2) & y \\ 1+y^2 & -xy & -x \\ -y & x & 0 \end{pmatrix}. \end{aligned}$$

Note that the ratio ρ_Z can be obtained directly from the partial pose estimation algorithm that will be described in Sect. 34.6.

If we come back to the usual global representation of visual servo control schemes, we have $e = (e_t, \theta u)$

and \mathbf{L}_e given by

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{L}_v & \mathbf{L}_\omega \\ 0 & \mathbf{L}_{\theta u} \end{pmatrix},$$

from which we immediately obtain the control law (34.27) and (34.28) by applying (34.5).

The behavior obtained using this choice for s_t is shown in Fig. 34.12 and VIDEO 64. Here, the point that has been considered in s_t is the center of gravity x_g of the target. We note the image trajectory of that point, which is a straight line as expected, and the nice decreasing of the camera velocity components, which makes this scheme very similar to the first PBVS one.

As for stability, it is clear that this scheme is globally asymptotically stable in perfect conditions. Furthermore, thanks to the triangular form of the interaction matrix \mathbf{L}_e , it is possible to analyze the stability of this scheme in the presence of calibration errors using the partial pose-estimation algorithm that will be described in Sect. 34.6 [34.37]. Finally, the only unknown constant parameter involved in this scheme, that is Z^* , can be estimated online using adaptive techniques [34.38].

Other hybrid schemes can be designed. For instance, in [34.39], the third component of s_t is different and has been selected so that all the target points remain in the camera field of view as far as possible. Another example has been proposed in [34.40]. In that case, s is selected as $s = ({}^c t_c, x_g, \theta u_z)$ which provides with a block-triangular interaction matrix of the form

$$\mathbf{L}_e = \begin{pmatrix} \mathbf{R} & 0 \\ \mathbf{L}'_v & \mathbf{L}'_\omega \end{pmatrix},$$

where \mathbf{L}'_v and \mathbf{L}'_ω can easily be computed. This scheme is such that, under perfect conditions, the camera trajectory is a straight line (since ${}^c t_c$ is a part of s), and the image trajectory of the center of gravity of the object is also a straight line (since x_g is also a part of s). The translational camera degrees of freedom are devoted to realize the 3-D straight line, while the rotational camera degrees of freedom are devoted to realize the 2-D straight line and also compensate the 2-D motion of x_g due to the translational motion. As can be seen in Fig. 34.13 and VIDEO 65, this scheme is particularly satisfactory in practice.

Finally, it is possible to combine 2-D and 3-D features in different ways. For instance, in [34.41], it has been proposed to use in s the 2-D homogeneous coordinates of a set of image points expressed in pixels multiplied by their corresponding depth:

Fig. 34.12 2.5-D VS system behavior using $s = (\mathbf{x}_g, \log(Z_g), \theta_u)$ (refer to Fig. 34.2a-c for description)

Fig. 34.13 2.5-D VS system behavior using $s = (c^* t_c, \mathbf{x}_g, \theta_{u_z})$ (refer to Fig. 34.2a-c for description)

$s = (u_1 Z_1, v_1 Z_1, Z_1, \dots, u_n Z_n, v_n Z_n, Z_n)$. As for classical IBVS, we obtain in this case a set of redundant features, since at least three points have to be used to control the six camera degrees of freedom (here $k \geq 9$). However, it has been demonstrated in [34.42] that this selection of redundant features is free of attractive local minima.

34.4.2 Partitioned VS

The hybrid visual servo schemes described above have been designed to decouple the rotational motions from the translational ones by selecting adequate visual features defined in part in 2-D, and in part in 3-D (which is why they have been called 2.5-D visual servoing). This work has inspired some researchers to find features that exhibit similar decoupling properties but using only features expressed directly in the image. More precisely, the goal is to find six features such that each is related to only one degree of freedom (in which case the interaction matrix is a diagonal matrix). The Grail is to find a diagonal interaction matrix whose elements are constant, as near as possible to the identity matrix, leading to a pure, direct, and simple linear control problem.

The first work in this area partitioned the interaction matrix to isolate motion related to the optic axis [34.12].

Indeed, whatever the choice of s , we have

$$\begin{aligned}\dot{s} &= \mathbf{L}_s \mathbf{v}_c \\ &= \mathbf{L}_{xy} \mathbf{v}_{xy} + \mathbf{L}_z \mathbf{v}_z \\ &= \dot{s}_{xy} + \dot{s}_z\end{aligned}$$

in which \mathbf{L}_{xy} includes the first, second, fourth, and fifth columns of \mathbf{L}_s , and \mathbf{L}_z includes the third and sixth columns of \mathbf{L}_s . Similarly, $\mathbf{v}_{xy} = (v_x, v_y, \omega_x, \omega_y)$ and $\mathbf{v}_z = (v_z, \omega_z)$. Here, $\dot{s}_z = \mathbf{L}_z \mathbf{v}_z$ gives the component of \dot{s} due to the camera motion along and rotation about the optic axis, while $\dot{s}_{xy} = \mathbf{L}_{xy} \mathbf{v}_{xy}$ gives the component of \dot{s} due to velocity along and rotation about the camera x and y axes.

Proceeding as above, by setting $\dot{e} = -\lambda e$ we obtain

$$-\lambda e = \dot{e} = \dot{s} = \mathbf{L}_{xy} \mathbf{v}_{xy} + \mathbf{L}_z \mathbf{v}_z,$$

which leads to

$$\mathbf{v}_{xy} = -\mathbf{L}_{xy}^+ [\lambda e(t) + \mathbf{L}_z \mathbf{v}_z].$$

As before, we can consider $[\lambda e(t) + \mathbf{L}_z \mathbf{v}_z]$ as a modified error that incorporates the original error while taking into account the error that will be induced by \mathbf{v}_z .

Given this result, all that remains is to choose s and v_z . As for basic IBVS, the coordinates of a collection of image points can be used in s , while two new image features can be defined to determine v_z :

- Define α , with $0 \leq \alpha < 2\pi$, as the angle between the horizontal axis of the image plane and the directed line segment joining two feature points. It is clear that α is closely related to the rotation around the optic axis.

- Define σ^2 to be the area of the polygon defined by these points. Similarly, σ^2 is closely related to the translation along the optic axis.

Using these features, v_z has been defined in [34.12] as

$$\begin{cases} v_z &= \lambda_{v_z} \ln \frac{\sigma^*}{\sigma} , \\ \omega_z &= \lambda_{\omega_z} (\alpha^* - \alpha) . \end{cases}$$

34.5 Performance Optimization and Planning

In some sense, partitioned methods represent an effort to optimize system performance by assigning distinct features and controllers to individual degrees of freedom. In this way, the designer performs a sort of offline optimization when allocating controllers to degrees of freedom. It is also possible to explicitly design controllers that optimize various system performance measures. We describe a few of these in this section.

34.5.1 Optimal Control and Redundancy Framework

An example of such an approach is given in [34.43] and [34.44], in which linear quadratic Gaussian (LQG) control design is used to choose gains that minimize a linear combination of state and control inputs. This approach explicitly balances the trade-off between tracking errors (since the controller attempts to drive $s - s^*$ to zero) and robot motion. A similar control approach is proposed in [34.45] where joint limit avoidance is considered simultaneously with the positioning task.

It is also possible to formulate optimality criteria that explicitly express the observability of robot motion in the image. For example, the singular value decomposition of the interaction matrix reveals which degrees of freedom are most apparent and can thus be easily controlled, while the condition number of the interaction matrix gives a kind of global measure of the visibility of motion. This concept has been called resolvability in [34.46] and motion perceptibility in [34.47]. By selecting features and designing controllers that maximize these measures, either along specific degrees of freedom or globally, the performance of the visual servo system can be improved.

The constraints considered to design the control scheme using the optimal control approach may be contradictory in some cases, leading the system to fail due to local minima in the objective function to be min-

imized. For example, it may happen that the motion produced to move away from a robot joint limit is exactly the opposite of the motion produced toward the desired pose, which results in a zero global motion. To avoid this potential problem, it is possible to use the gradient projection method, which is classical in robotics. Applying this method to visual servoing has been proposed in [34.3, 19]. The approach consists of projecting the secondary constraints e_s onto the null space of the vision-based task e so that they have no effect on the regulation of e to 0

$$e_g = \widehat{\mathbf{L}}_e^+ e + \mathbf{P}_e e_s ,$$

where e_g is the new global task considered and

$$\mathbf{P}_e = (\mathbf{I}_6 - \widehat{\mathbf{L}}_e^+ \widehat{\mathbf{L}}_e)$$

is such that

$$\widehat{\mathbf{L}}_e \mathbf{P}_e e_s = 0 , \forall e_s .$$

Avoiding the robot joint limits using this approach has been presented in [34.48]. However, when the vision-based task constrains all the camera degrees of freedom, the secondary constraints cannot be considered since, when $\widehat{\mathbf{L}}_e$ is of full rank 6, we have $\mathbf{P}_e e_s = 0, \forall e_s$. In this case, it is necessary to insert the constraints into a global objective function, such as navigation functions that are free of local minima [34.49, 50].

34.5.2 Switching Schemes

The partitioned methods described previously attempt to optimize performance by assigning individual controllers to specific degrees of freedom. Another way to use multiple controllers to optimize performance is to design switching schemes that select at each moment

Fig. 34.14 Image feature trajectories for a rotation of 160° about the optical axis using a switched control scheme (initial point positions in *blue*, and desired points position in *red*)

in time which controller to use based on criteria to be optimized.

A simple switching controller can be designed using an **IBVS** and a **PBVS** controller as follows [34.51]. Let the system begin by using the **IBVS** controller. Consider the Lyapunov function for the **PBVS** controller given by $\mathcal{L}_P = \frac{1}{2} \|e_P(t)\|^2$, with $e_P(t) = ({}^c t_o - {}^{c*} t_o, \theta u)$. If at any time the value of this Lyapunov function exceeds a threshold γ_P , the system switches to the **PBVS** controller. While using the **PBVS** controller, if at any time the value of the Lyapunov function \mathcal{L}_I for the **IBVS** controller exceeds a threshold, $\mathcal{L}_I = \frac{1}{2} \|e_I(t)\|^2 > \gamma_I$, the system switches to the **IBVS** controller. With this scheme, when the Lyapunov function for a particular controller exceeds a threshold, that controller is invoked, which in turn reduces the value of the corresponding Lyapunov function. If the switching thresholds are selected appropriately, the system is able to exploit the relative advantages of **IBVS** and **PBVS**, while avoiding their shortcomings.

An example of such a system is shown in Fig. 34.14 for the case of a rotation by 160° about the optical axis. Note that the system begins in **IBVS** mode and the features initially move on straight lines toward their goal

positions in the image. However, as the camera retreats, the system switches to **PBVS**, which allows the camera to reach its desired position by combining a rotational motion around its optic axis and a forward translational motion, producing the circular trajectories observed in the image.

Other examples of temporal switching schemes can be found, such as the one developed in [34.52], to ensure the visibility of the target observed.

34.5.3 Feature Trajectory Planning

It is also possible to treat the optimization problem offline, during a planning stage, if we have sufficient knowledge of the system and world. In this case, several constraints can be taken into account simultaneously, such as obstacle avoidance [34.53], joint limit and occlusions avoidance, and ensuring the visibility of the target [34.54]. The feature trajectories $s^*(t)$ that allow the camera to reach its desired pose while ensuring that the constraints are satisfied are determined using path planning techniques, such as the well-known potential field approach [34.54] or linear matrix inequality optimizations [34.55].

Coupling path planning with trajectory following also allows the robustness of the visual servo with respect to modeling errors to be significantly improved. Indeed, modeling errors may have large effects when the error $s - s^*$ is large, but have little effect when $s - s^*$ is small. Once the desired features trajectories $s^*(t)$ such that $s^*(0) = s(0)$ have been designed during the planning stage, it is easy to adapt the control scheme to take into account the fact that s^* is varying, and to make the error $s - s^*$ remain small. More precisely, we now have

$$\dot{e} = \dot{s} - \dot{s}^* = \mathbf{L}_e v_c - \dot{s}^*,$$

from which we deduce, by selecting as usual $\dot{e} = -\lambda e$ as the desired behavior,

$$v_c = -\lambda \widehat{\mathbf{L}_e^+} e + \widehat{\mathbf{L}_e^+} \dot{s}^*.$$

The new second term of this control law anticipates the variation of s^* , removing the tracking error it would produce. We will see in the 34.8 that the form of the control law is similar when tracking of a moving target is considered.

34.6 Estimation of 3-D Parameters

All the control schemes described in the previous sections use 3-D parameters that are not directly available from the image measurements. As for IBVS, we recall that the range of the object with respect to the camera appears in the coefficients of the interaction matrix related to the translational degrees of freedom. Noticeable exceptions are the schemes based on a numerical estimation of \mathbf{L}_e or of \mathbf{L}_e^+ (Sect. 34.2.8). Another exception is the IBVS scheme that uses the constant matrix $\widehat{\mathbf{L}_e^+}$ in the control scheme, in which only the depth for the desired pose is required, which is not so difficult to obtain in practice. As for PBVS and hybrid schemes that combine 2-D and 3-D data in e , 3-D parameters appear both in the error e and in the interaction matrix. A correct estimation of the 3-D parameters involved is thus important for IBVS since they will have an effect on the camera motion during the task execution (they appear in the stability conditions (34.13) and (34.14)), while a correct estimation is crucial in PBVS and hybrid schemes since they will have also an effect on the accuracy of the pose reached after convergence.

If a calibrated stereo vision system is used, all 3-D parameters can be easily determined by triangulation, as mentioned in Sect. 34.2.5 and described in Chap. 32. Similarly, if a 3-D model of the object is known, all 3-D parameters can be computed from a pose-estimation algorithm. However, we recall that such an estimation can be quite unstable due to image noise (Sect. 34.3). As already said, IBVS does not require full pose estimation, simply the range of the object with respect to the camera. When image points are involved in s , the range is expressed as the scalar depth Z or distance R of the corresponding world points, which appears in the interaction matrix (34.12), (34.16) and (34.17). This can be considered as a parameter estimation problem, that is, estimating the 3-D parameters from knowledge of the analytical form of the interaction matrix, and measurements of camera motion and visual feature position and velocity [34.56–58].

It is also possible to estimate 3-D parameters by using the epipolar geometry that relates the images of the same scene observed from different viewpoints. Indeed, in visual servoing, two images are generally available: the current one and the desired one. Given a set of matches between the image measurements in the current image and in the desired one, the fundamental matrix, or the essential matrix if the camera is calibrated, can be recovered [34.6], and then used in visual servoing [34.59]. Indeed, from the essential matrix, the rotation and the translation up to a scalar factor between the two views can be estimated. However, near the con-

vergence of the visual servo, that is, when the current and desired images are similar, the epipolar geometry becomes degenerate and it is not possible to estimate accurately the partial pose between the two views. For this reason, using homography is generally preferred.

Let \mathbf{x}_i and \mathbf{x}_i^* denote the homogeneous image coordinates for a point in the current and desired images. Then \mathbf{x}_i is related to \mathbf{x}_i^* by

$$\mathbf{x}_i = \mathbf{H}_i \mathbf{x}_i^*$$

in which \mathbf{H}_i is a homography matrix.

If all feature points lie on a 3-D plane, then there is a single homography matrix \mathbf{H} such that $\mathbf{x}_i = \mathbf{H} \mathbf{x}_i^*$ for all i . This homography can be estimated using the position of four matched points in the desired and the current images. If all the features points do not belong to the same 3-D plane, then three points can be used to define such a plane and five supplementary points are needed to estimate \mathbf{H} [34.60].

Once \mathbf{H} is available, it can be decomposed as

$$\mathbf{H} = \mathbf{R} + \frac{\mathbf{t}}{d^*} \mathbf{n}^{*T}, \quad (34.29)$$

in which \mathbf{R} is the rotation matrix relating the orientation of the current and desired camera frames, \mathbf{n}^* is the normal to the chosen 3-D plane expressed in the desired frame, d^* is the distance to the 3-D plane from the desired frame, and \mathbf{t} is the translation between current and desired frames. From \mathbf{H} , it is thus possible to recover \mathbf{R} , \mathbf{t}/d^* , and \mathbf{n} . In fact, two solutions for these quantities exist [34.61], but it is quite easy to select the correct one using some knowledge about the desired pose. It is also possible to estimate the depth of any target point up to a common scale factor [34.54]. The unknown depth of each point that appears in classical IBVS can thus be expressed as a function of a single, constant parameter whatever the number of points. Similarly, the pose parameters required by PBVS can be recovered up to a scalar factor as for the translation term. The PBVS schemes described previously can thus be revisited using this approach, with the new error defined as the translation up to a scalar factor and the angle/axis parameterization of the rotation. This approach has also been used for the hybrid visual servoing schemes described in Sect. 34.4.1. In that case, using such homography estimation, it has been possible to analyze the stability of hybrid visual servoing schemes in the presence of calibration errors [34.36]. Finally, it is also possible to directly use the homography in the control scheme, avoiding thus its decomposition as a partial pose [34.62].

34.7 Determining s^* and Matching Issues

All visual servo methods require knowledge of the desired feature values s^* which implicitly define constraints on the desired camera or robot pose with respect to the target. Three common approaches are employed. The first is when the task is directly specified as a desired value of some features to be reached. This is the case for instance when a target has to be centered in the image. This is also the case when the task is specified as a particular pose to reach and a PBVS is chosen. In that case however, the camera will reach its desired pose only if the camera is perfectly calibrated. Indeed, a coarse camera calibration will induce a biased estimation of the pose, which will make the final pose different from the desired one.

For IBVS and hybrid schemes, the second approach is to use knowledge of the object and camera projection models to compute s^* for the desired relative pose. Once again, the accuracy of the system directly depends on the camera calibration, since the camera intrinsic parameters are involved to compute s^* .

Finally, the third approach is to simply record the feature values s^* when the camera or robot has the desired pose with respect to the target. This is usually done during an off-line teaching step. When it is possible in practice, this approach is very efficient since the positioning accuracy does not depend anymore on the camera calibration. This is still true for PBVS since, even if the pose estimated from the desired image is biased due to calibration errors, the same biased pose will be estimated once the robot will have converged so that the final image acquired by the camera will be the desired one.

So far we have not commented on the matching issues involved in visual servo methods. Two cases can be differentiated in function of the nature of the components of s . When some components of s come from a pose estimation, it is necessary to match the measurements in the image (usually some image points) to the model of the object (usually some world points). Incorrect association will lead to an erroneous estimation of the pose. In all other cases, the calculation of the error vector e defined in (34.1) necessitates a matching between the measurements $m(t)$ in the current image and m^* in the desired image. For instance, in all IBVS examples presented above, the camera observes four image points and we need to determine which of the four desired points to associate with each observed point so that the visual features s are correctly associated to their desired value s^* . Incorrect association will lead to incorrect final camera pose and possibly a configuration which can not be achieved from any real camera pose. If we want to use the epipolar geometry or estimate a homography matrix, a similar matching process is necessary (Sect. 34.6).

This matching process is a classical computer vision problem. Note that it may be particularly difficult for the very first image, especially when the robot displacement to achieve is large, which generally implies large disparities between the initial and desired images. Once the association has been correctly performed for the very first image, the matching is greatly simplified since it transforms to a visual tracking problem where the results obtained for the previous image can be used as initialization for the current one.

34.8 Target Tracking

We now consider the case of a moving target and a constant desired value s^* for the features, the generalization to varying desired features $s^*(t)$ being immediate. The time variation of the error is now given by

$$\dot{e} = L_e v_c + \frac{\partial e}{\partial t}, \quad (34.30)$$

where the term $\partial e / \partial t$ expresses the time variation of e due to the generally unknown target motion. If the control law is still designed to try to ensure an exponential decoupled decrease of e (that is, once again $\dot{e} = -\lambda e$), we now obtain using (34.30)

$$v_c = -\lambda \widehat{L_e^+} e - \widehat{L_e^+} \frac{\partial e}{\partial t}, \quad (34.31)$$

where $\widehat{\partial e / \partial t}$ is an estimation or an approximation of $\partial e / \partial t$. This term must be introduced into the control law to compensate for the target motion.

Closing the loop, that is, inserting (34.31) into (34.30), we obtain

$$\dot{e} = -\lambda L_e \widehat{L_e^+} e - L_e \widehat{L_e^+} \frac{\partial e}{\partial t} + \frac{\partial e}{\partial t}. \quad (34.32)$$

Even if $L_e \widehat{L_e^+} > 0$, the error will converge to zero only if the estimation of $\widehat{\partial e / \partial t}$ is sufficiently accurate so that

$$L_e \widehat{L_e^+} \frac{\partial e}{\partial t} = \frac{\partial e}{\partial t}, \quad (34.33)$$

otherwise tracking errors will be observed. Indeed, by just solving the scalar differential equation $\dot{e} = -\lambda e + b$, which is a simplification of (34.32), we obtain $e(t) = e(0) \exp(-\lambda t) + b/\lambda$, which converges towards b/λ . On one hand, setting a high gain λ will reduce the tracking error, but on the other hand, setting the gain too high can make the system unstable. It is thus necessary to make b as small as possible.

Of course, if the system is known to be such that $\partial e / \partial t = 0$ (that is, the camera observes a motionless object, as described in Sect. 34.1), no tracking error will appear with the most simple estimation given by $\widehat{\partial e / \partial t} = 0$. Otherwise, a classical method in automatic control to cancel tracking errors consists of compensating the target motion through an integral term in the control law. In this case, we have

$$\widehat{\frac{\partial e}{\partial t}} = \mu \sum_j e(j),$$

where μ is the integral gain that has to be tuned. This scheme allows the tracking errors to be canceled only if

the target has a constant velocity. Other methods, based on feedforward control, estimate the term $\widehat{\partial e / \partial t}$ directly through the image measurements and the camera velocity, when it is available. Indeed, from (34.30), we obtain

$$\widehat{\frac{\partial e}{\partial t}} = \hat{e} - \hat{\mathbf{L}}_e \hat{v}_c,$$

where \hat{e} can, for instance, be obtained as $\hat{e}(t) = [e(t) - e(t - \Delta t)] / \Delta t$, Δt being the duration of the control loop. A Kalman filter [34.63] or more-elaborate filtering methods [34.64] can then be used to improve the estimated values obtained. If some knowledge about the target velocity or the target trajectory is available, it can of course be used to smooth or predict the motion [34.65–67]. For instance, in [34.68], the periodic motion of the heart and breathing are compensated for an application of visual servoing in medical robotics. Finally, other methods have been developed to remove the perturbations induced by the target motion as fast as possible [34.43], using for instance predictive controllers [34.69].

34.9 Eye-in-Hand and Eye-to-Hand Systems Controlled in the Joint Space

In the previous sections, we have considered the six components of the camera velocity as the input of the robot controller. As soon as the robot is not able to realize this motion, for instance, because it has fewer than six degrees of freedom, the control scheme must be expressed in the joint space. In this section, we describe how this can be done, and in the process develop a formulation for eye-to-hand systems.

In the joint space, the system equations for both the eye-to-hand and eye-in-hand configurations have the same form

$$\dot{s} = \mathbf{J}_s \dot{q} + \frac{\partial s}{\partial t}. \quad (34.34)$$

Here, $\mathbf{J}_s \in \mathbb{R}^{k \times n}$ is the feature Jacobian matrix, which can be linked to the interaction matrix, and n is the number of robot joints.

For an eye-in-hand system (Fig. 34.15a), $\partial s / \partial t$ is the time variation of s due to a potential object motion, and \mathbf{J}_s is given by

$$\mathbf{J}_s = \mathbf{L}_s {}^c X_N \mathbf{J}(q), \quad (34.35)$$

where:

- ${}^c X_N$ is the spatial motion transform matrix (as defined in Chap. 02 and recalled in (34.15)) from the vision sensor frame to the end-effector frame. It is usually a constant matrix (as long as the vision sensor is rigidly attached to the end-effector). Thanks to the robustness of closed-loop control schemes, a coarse approximation of this transform matrix is sufficient in visual servoing. If needed, an accurate estimation is possible through classical hand-eye calibration methods [34.70].
- $\mathbf{J}(q)$ is the robot Jacobian expressed in the end-effector frame (as defined in Chap. 02)

For an eye-to-hand system (Fig. 34.15b), $\partial s / \partial t$ is now the time variation of s due to a potential vision sensor motion and \mathbf{J}_s can be expressed as

$$\mathbf{J}_s = -\mathbf{L}_s {}^c X_N {}^N \mathbf{J}(q), \quad (34.36)$$

$$= -\mathbf{L}_s {}^c X_0 {}^0 \mathbf{J}(q). \quad (34.37)$$

In (34.36), the classical robot Jacobian ${}^N \mathbf{J}(q)$ expressed in the end-effector frame is used but the spatial motion transform matrix ${}^c X_N$ from the vision sensor frame to the end-effector frame changes all along the robot mo-

Fig.34.15a,b (a) Eye-in-hand system, (b) eye-to-hand system: system schematic (top) and opposite image motion produced by the same robot motion (bottom)

tion, and it has to be estimated at each iteration of the control scheme, usually using pose-estimation methods.

In (34.37), the robot Jacobian ${}^0\mathbf{J}(\mathbf{q})$ is expressed in the robot reference frame, and the spatial motion transform matrix ${}^c\mathbf{X}_0$ from the vision sensor frame to that reference frame is constant as long as the camera does not move. In this case, which is convenient in practice, a coarse approximation of ${}^c\mathbf{X}_0$ is usually sufficient.

Once the modeling step is finished, it is quite easy to follow the procedure that has been used above to design a control scheme expressed in the joint space, and to determine the sufficient condition to ensure the stability of the control scheme. We obtain, considering again $\mathbf{e} = \mathbf{s} - \mathbf{s}^*$, and an exponential decoupled decrease of \mathbf{e}

$$\dot{\mathbf{q}} = -\lambda \widehat{\mathbf{J}}_e^+ \mathbf{e} - \widehat{\mathbf{J}}_e^+ \frac{\partial \mathbf{e}}{\partial t}. \quad (34.38)$$

If $k = n$, considering as in Sect. 34.1 the Lyapunov function $\mathcal{L} = \frac{1}{2} \|\mathbf{e}(t)\|^2$, a sufficient condition to ensure

the global asymptotic stability is given by

$$\mathbf{J}_e \widehat{\mathbf{J}}_e^+ > 0. \quad (34.39)$$

If $k > n$, we obtain similarly to Sect. 34.1

$$\widehat{\mathbf{J}}_e^+ \mathbf{J}_e > 0 \quad (34.40)$$

to ensure the local asymptotic stability of the system. Note that the actual extrinsic camera parameters appear in \mathbf{J}_e while the estimated ones are used in $\widehat{\mathbf{J}}_e^+$. It is thus possible to analyze the robustness of the control scheme with respect to the camera extrinsic parameters. It is also possible to estimate directly the numerical value of \mathbf{J}_e or $\widehat{\mathbf{J}}_e^+$ using the methods described in Sect. 34.2.8.

Finally, to remove tracking errors, we have to ensure that

$$\mathbf{J}_e \widehat{\mathbf{J}}_e^+ \frac{\partial \mathbf{e}}{\partial t} = \frac{\partial \mathbf{e}}{\partial t}.$$

Let us note that, even if the robot has six degrees of freedom, it is generally not equivalent to first compute \mathbf{v}_c using (34.5) and then deduce $\dot{\mathbf{q}}$ using the robot inverse Jacobian, and to compute directly $\dot{\mathbf{q}}$ using (34.38). Indeed, it may occur that the robot Jacobian $\mathbf{J}(\mathbf{q})$ is singular while the feature Jacobian \mathbf{J}_s is not (that may occur when $k < n$). Furthermore, the properties of the pseudo-inverse ensure that using (34.5), $\|\mathbf{v}_c\|$ is minimal while using (34.38), $\|\dot{\mathbf{q}}\|$ is minimal. As soon as

$$\mathbf{J}_e^+ \neq \mathbf{J}^+(\mathbf{q})^N \mathbf{X}_c \mathbf{L}_e^+,$$

the control schemes will be different and will induce different robot trajectories. The choice of the state space is thus important.

34.10 Under Actuated Robots

Many useful robots are under actuated, that is, they cannot move instantaneously in all directions because of the number or configuration of their actuators (Chap. 52). For instance, a quadrotor flying robot is under actuated since it has only four actuators while the dimension of its configuration space is six. Many other useful robots are subject to non-holonomic constraints (Chap. 49), leading to similar motion inability. A car for instance has only two degrees of freedom (for velocity and steering) while the dimension of its configuration space is three (position and orientation in the ground plane).

A consequence of under actuation is that time varying manoeuvres may be required in order to achieve particular goal states. For example, if a quadrotor has to move forward, it must first change its attitude, pitching down, so that a component of its thrust vector is able to accelerate the vehicle forward. For a visual servo system this can be problematic since the initial attitude change will affect the value of the visual features even before the vehicle has moved. In fact the attitude change increases the error and this is ultimately destabilising.

A common and expedient solution [34.71] is to *de-rotate* the image, that is, to use information from

a non-vision attitude sensor such as an inertial measurement unit (IMU) (Chap. 29) to correct the feature coordinates as if they had been viewed by a virtual camera whose optical axis has a constant orientation in space, typically, straight down. As discussed in Sect. 34.2.8, the spherical projection model is well suited for such image transformation, thanks to its invariance properties with respect to rotational motion.

For a non-holonomic vehicle, there are several solutions. In the non-general case where the vehicle is able to follow a smooth path from its initial to goal

configuration, a controller based on visually estimated relative pose (range, heading angle and lateral offset) can be used (Chap. 49), following a PBVS strategy. Particular controllers based on the epipolar geometry or the trifocal tensor have also been designed [34.72, 73]. For the more general case, switching control laws can be used. If possible in practice, another common solution is to add a controlled DOF between the vehicle and the camera in order to bypass the non-holonomic constraint through redundancy. It is thus possible to control the full camera configuration, but not the robot one.

Fig. 34.16 Few applications of visual servoing: Gaze control for target tracking, navigation of a mobile robot to follow a wall using an omnidirectional vision sensor, grasping a ball with a humanoid robot, assembly of MEMS and film of a dialogue within the constraints of a script in animation

34.11 Applications

Applications of visual servoing in robotics are numerous. It can be used as soon as a vision sensor is available and a task is assigned to a dynamic system to control its motion. A non exhaustive list of examples are (Fig. 34.16):

- The control of a pan-tilt-zoom camera for target tracking
- Grasping using a robot arm
- Locomotion and dextrous manipulation with a humanoid robot
- Micro or nano manipulation of microelectromechanical system (MEMS) or biological cells
- Accurate positioning of a parallel robot
- Pipe inspection by an underwater autonomous vehicle
- Autonomous navigation of a mobile robot in indoor or outdoor environment
- Aircraft landing
- Autonomous satellite rendezvous
- Biopsy using ultrasound probes or heart motion compensation in medical robotics
- Virtual cinematography in animation.

Software are available to help any user interested in developing visual servoing applications. We recommend the Robotics, Machine Vision Toolbox for Matlab [34.74] and the ViSP C++ library [34.11].

34.12 Conclusions

In this chapter we have only considered velocity controllers, which are convenient for most classical robot arms. However, the dynamics of the robot must of course be taken into account for high-speed tasks. Features related to the image motion [34.75], image intensity [34.76], or coming from other vision sensors (RGB-D sensors, ultrasonic probes [34.77], etc.) neces-

sitate reconsideration of the modeling issues to select adequate visual features. Finally, fusing visual features with data coming from other sensors (force sensor, proximity sensors, etc.) at the level of the control scheme will allow new research topics to be addressed. The end of fruitful research in the field of visual servo is thus nowhere yet in sight.

Hugh Durrant-Whyte, Thomas C. Henderson

Multisensor data fusion is the process of combining observations from a number of different sensors to provide a robust and complete description of an environment or process of interest. Data fusion finds wide application in many areas of robotics such as object recognition, environment mapping, and localization.

This chapter has three parts: methods, architectures, and applications. Most current data fusion methods employ probabilistic descriptions of observations and processes and use Bayes' rule to combine this information. This chapter surveys the main probabilistic modeling and fusion techniques including grid-based models, Kalman filtering, and sequential Monte Carlo techniques. This chapter also briefly reviews a number of nonprobabilistic data fusion methods. Data fusion systems are often complex combinations of sensor devices, processing, and fusion algorithms. This chapter provides an overview of key principles in data fusion architectures from both a hardware and algorithmic viewpoint. The applications of data fusion are pervasive in robotics and underly the core problem of sensing, estimation, and perception. We highlight two example applications that bring out these features. The first describes a navigation or self-tracking application for an autonomous vehicle. The second describes an application in mapping and environment modeling.

The essential algorithmic tools of data fusion are reasonably well established. However, the development and use of these tools in realistic robotics applications is still developing.

35.1 Multisensor Data Fusion Methods

The most widely used data fusion methods employed in robotics originate in the fields of statistics, estimation, and control. However, the application of these methods in robotics has a number of unique features and

challenges. In particular, autonomy is most often the goal and so results must be presented and interpreted in a form from which autonomous decisions can be made, for recognition or navigation, for example.

In this section we review the main data fusion methods employed in robotics. These are very often based on probabilistic methods, which are indeed now considered the standard approach to data fusion in all robotics applications [35.1]. Probabilistic data fusion methods are generally based on Bayes' rule for combining prior and observation information. Practically, this may be implemented in a number of ways: through the use of the Kalman and extended Kalman filters, through sequential Monte Carlo methods, or through the use of functional density estimates. Each of these is reviewed. There are a number of alternatives to probabilistic methods. These include the theory of evidence and interval methods. Such alternative techniques are not as widely used as they once were, however they have some special features that can be advantageous in specific problems. These, too, are briefly reviewed.

35.1.1 Bayes' Rule

Bayes' rule lies at the heart of most data fusion methods. In general, Bayes' rule provides a means to make inferences about an object or environment of interest described by a state \mathbf{x} , given an observation \mathbf{z} .

Bayesian Inference

Bayes' rule requires that the relationship between \mathbf{x} and \mathbf{z} be encoded as a joint probability or joint probability distribution $P(\mathbf{x}, \mathbf{z})$ for discrete and continuous variables, respectively. The chain rule of conditional probabilities can be used to expand a joint probability in two ways

$$P(\mathbf{x}, \mathbf{z}) = P(\mathbf{x} | \mathbf{z})P(\mathbf{z}) = P(\mathbf{z} | \mathbf{x})P(\mathbf{x}). \quad (35.1)$$

Rearranging in terms of one of the conditionals, Bayes' rule is obtained

$$P(\mathbf{x} | \mathbf{z}) = \frac{P(\mathbf{z} | \mathbf{x})P(\mathbf{x})}{P(\mathbf{z})}. \quad (35.2)$$

The value of this result lies in the interpretation of the probabilities $P(\mathbf{x} | \mathbf{z})$, $P(\mathbf{z} | \mathbf{x})$, and $P(\mathbf{x})$. Suppose it is necessary to determine the various likelihoods of different values of an unknown state \mathbf{x} . There may be prior beliefs about what values of \mathbf{x} might be expected, encoded in the form of relative likelihoods in the *prior probability* $P(\mathbf{x})$. To obtain more information about the state \mathbf{x} an observation \mathbf{z} is made. These observations are modeled in the form of a conditional probability $P(\mathbf{z} | \mathbf{x})$ that describes, for each fixed state \mathbf{x} , the probability that the observation \mathbf{z} will be made, i. e., the probability of \mathbf{z} given \mathbf{x} . The new likelihoods associated with

the state \mathbf{x} are computed from the product of the original prior information and the information gained by observation. This is encoded in the *posterior probability* $P(\mathbf{x} | \mathbf{z})$, which describes the likelihoods associated with \mathbf{x} given the observation \mathbf{z} . In this fusion process, the marginal probability $P(\mathbf{z})$ simply serves to normalize the posterior and is not generally computed. The marginal $P(\mathbf{z})$ plays an important role in model validation or data association as it provides a measure of how well the observation is predicted by the prior, because $P(\mathbf{z}) = \int P(\mathbf{z} | \mathbf{x})P(\mathbf{x})d\mathbf{x}$. The value of Bayes' rule is that it provides a principled means of combining observed information with prior beliefs about the state of the world.

Sensor Models and Multisensor Bayesian Inference

The conditional probability $P(\mathbf{z} | \mathbf{x})$ serves the role of a *sensor model* and can be thought of in two ways. First, in building a sensor model, the probability is constructed by fixing the value of $\mathbf{x} = \mathbf{x}$ and then asking what probability density $P(\mathbf{z} | \mathbf{x} = \mathbf{x})$ on \mathbf{z} results. Conversely, when this sensor model is used and observations are made, $\mathbf{z} = \mathbf{z}$ is fixed and a *likelihood function* $P(\mathbf{z} = \mathbf{z} | \mathbf{x})$ on \mathbf{x} is inferred. The likelihood function, while not strictly a probability density, models the relative likelihood that different values of \mathbf{x} gave rise to the observed value of \mathbf{z} . The product of this likelihood with the prior, both defined on \mathbf{x} , gives the posterior or observation update $P(\mathbf{x} | \mathbf{z})$. In a practical implementation of (35.2), $P(\mathbf{z} | \mathbf{x})$ is constructed as a function of both variables (or a matrix in discrete form). For each fixed value of \mathbf{x} , a probability density on \mathbf{z} is defined. Therefore, as \mathbf{x} varies, a family of likelihoods on \mathbf{z} is created.

The multisensor form of Bayes' rule requires conditional independence

$$\begin{aligned} P(\mathbf{z}_1, \dots, \mathbf{z}_n | \mathbf{x}) &= P(\mathbf{z}_1 | \mathbf{x}) \cdots P(\mathbf{z}_n | \mathbf{x}) \\ &= \prod_{i=1}^n P(\mathbf{z}_i | \mathbf{x}), \end{aligned} \quad (35.3)$$

so that

$$P(\mathbf{x} | \mathbf{Z}^n) = C P(\mathbf{x}) \prod_{i=1}^n P(\mathbf{z}_i | \mathbf{x}), \quad (35.4)$$

where C is a normalizing constant. Equation 35.4 is known as the *independent likelihood pool* [35.2]. This states that the posterior probability on \mathbf{x} given all observations \mathbf{Z}^n , is simply proportional to the product of prior probability and individual likelihoods from each information source.

The recursive form of Bayes' rule is

$$P(\mathbf{x} | \mathbf{Z}^k) = \frac{P(\mathbf{z}_k | \mathbf{x})P(\mathbf{x} | \mathbf{Z}^{k-1})}{P(\mathbf{z}_k | \mathbf{Z}^{k-1})}. \quad (35.5)$$

The advantage of (35.5) is that we need to compute and store only the posterior density $P(\mathbf{x} | \mathbf{Z}^{k-1})$, which contains a complete summary of all past information. When the next piece of information $P(\mathbf{z}_k | \mathbf{x})$ arrives, the previous posterior takes on the role of the current prior and the product of the two becomes, when normalized, the new posterior.

Bayesian Filtering

Filtering is concerned with the sequential process of maintaining a probabilistic model for a state which evolves over time and which is periodically observed by a sensor. Filtering forms the basis for many problems in tracking and navigation. The general filtering problem can be formulated in Bayesian form. This is significant because it provides a common representation for a range of discrete and continuous data fusion problems without recourse to specific target or observation models.

Define \mathbf{x}_t as the value of a state of interest at time t . This may, for example, describe a feature to be tracked, the state of a process being monitored, or the location of a platform for which navigation data is required. For convenience, and without loss of generality, time is defined at discrete (asynchronous) times $t_k \triangleq k$. At a time instant k , the following quantities are defined:

- \mathbf{x}_k : The state vector to be estimated at time k .
- \mathbf{u}_k : A control vector, assumed known, and applied at time $k-1$ to drive the state from \mathbf{x}_{k-1} to \mathbf{x}_k at time k .
- \mathbf{z}_k : An observation taken of the state \mathbf{x}_k at time k .

In addition, the following sets are also defined:

- The history of states:
 $\mathbf{X}^k = \{\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_k\} = \{\mathbf{X}^{k-1}, \mathbf{x}_k\}.$
- The history of control inputs:
 $\mathbf{U}^k = \{\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_k\} = \{\mathbf{U}^{k-1}, \mathbf{u}_k\}.$
- The history of state observations:
 $\mathbf{Z}^k = \{\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_k\} = \{\mathbf{Z}^{k-1}, \mathbf{z}_k\}.$

In probabilistic form, the general data fusion problem is to find the posterior density

$$P(\mathbf{x}_k | \mathbf{Z}^k, \mathbf{U}^k, \mathbf{x}_0) \quad (35.6)$$

for all times k given the recorded observations and control inputs up to and including time k together (possibly) with knowledge of the initial state \mathbf{x}_0 . Bayes'

rule can be used to write (35.6) in terms of a sensor model $P(\mathbf{z}_k | \mathbf{x}_k)$ and a predicted probability density $P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0)$ based on observations up to time $k-1$ as

$$\begin{aligned} P(\mathbf{x}_k | \mathbf{Z}^k, \mathbf{U}^k, \mathbf{x}_0) \\ = \frac{P(\mathbf{z}_k | \mathbf{x}_k)P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0)}{P(\mathbf{z}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k)}. \end{aligned} \quad (35.7)$$

The denominator in (35.7) is independent of the state and following (35.4) can be set to some normalizing constant C . The sensor model makes use of the conditional independence assumption from (35.3).

The total probability theorem can be used to rewrite the second term in the numerator of (35.7) in terms of the state transition model and the joint posterior from time step $k-1$ as

$$\begin{aligned} P(\mathbf{x}_k | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) \\ = \int P(\mathbf{x}_k, \mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) d\mathbf{x}_{k-1} \\ = \int P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) \\ \times P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^k, \mathbf{x}_0) d\mathbf{x}_{k-1} \\ = \int P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k) \\ \times P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}, \mathbf{U}^{k-1}, \mathbf{x}_0) d\mathbf{x}_{k-1}, \end{aligned} \quad (35.8)$$

where the last equality implies that the future state depends only on the current state and the control exerted at this time. The state transition model is described in terms of a probability distribution in the form $P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k)$. That is, the state transition may reasonably be assumed to be a Markov process in which the next state \mathbf{x}_k depends only on the immediately preceding state \mathbf{x}_{k-1} and the applied control \mathbf{u}_k , and is independent of both the observations and preceding states.

Equations (35.7) and (35.8) define a recursive solution to (35.6). Equation (35.8) is the *time update* or *prediction* step for the full Bayes data fusion algorithm. A graphical description of this equation is shown in Fig. 35.1. Equation (35.7) is the *observation update* step for the full Bayes data fusion algorithm. A graphical description of this equation is shown in Fig. 35.2. The Kalman filter, grid-based methods, and sequential Monte Carlo methods, to be described, are specific implementations of these general equations.

35.1.2 Probabilistic Grids

Probabilistic grids are conceptually the simplest way of implementing Bayesian data fusion methods. They can

Fig. 35.1 Time update step for the full Bayes filter. At a time $k-1$, knowledge of the state \mathbf{x}_{k-1} is summarized in a probability distribution $P(\mathbf{x}_{k-1})$. A vehicle model, in the form of a conditional probability density $P(\mathbf{x}_k | \mathbf{x}_{k-1})$, then describes the stochastic transition of the vehicle from a state \mathbf{x}_{k-1} at a time $k-1$ to a state \mathbf{x}_k at a time k . Functionally, this state transition may be related to an underlying kinematic state model in the form $\mathbf{x}_k = f(\mathbf{x}_{k-1}, \mathbf{u}_k)$. The figure shows two typical conditional probability distributions $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ on the state \mathbf{x}_k given fixed values of \mathbf{x}_{k-1} . The product of this conditional distribution with the marginal distribution $P(\mathbf{x}_{k-1})$, describing the prior likelihood of values of \mathbf{x}_k , gives the joint distribution $P(\mathbf{x}_k, \mathbf{x}_{k-1})$ shown as the surface in the figure. The total marginal density $P(\mathbf{x}_k)$ describes knowledge of \mathbf{x}_k after state transition has occurred. The marginal density $P(\mathbf{x}_k)$ is obtained by integrating (projecting) the joint distribution $P(\mathbf{x}_k, \mathbf{x}_{k-1})$ over all \mathbf{x}_{k-1} . Equivalently, using the total probability theorem, the marginal density can be obtained by integrating (summing) all conditional densities $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ weighted by the prior probability $P(\mathbf{x}_{k-1})$ of each \mathbf{x}_{k-1} . The process can equally be run in reverse (a retroverse motion model) to obtain $P(\mathbf{x}_{k-1})$ from $P(\mathbf{x}_k)$ given a model $P(\mathbf{x}_{k-1} | \mathbf{x}_k)$.

be applied both to problems in mapping [35.3, 4] and tracking [35.5].

In mapping applications, the environment of interest is divided into a grid of equally sized spatial cells. Each cell is indexed and labeled with a property, thus the state \mathbf{x}_{ij} may describe a two-dimensional world indexed by ij and having the property x . Interest is focused on maintaining a probability distribution on possible state values $P(\mathbf{x}_{ij})$ at each grid cell. Typically, in navigation and mapping problems, the property of interest has only two values O and E , *occupied* and

empty, respectively, and it is then usual to assume that $P(\mathbf{x}_{ij} = O) = 1 - P(\mathbf{x}_{ij} = E)$. However, there is no particular constraint on the property encoded by the state \mathbf{x}_{ij} which could have many values (green, red, blue, for example) and indeed be continuous (the temperature at a cell, for example).

Once the state has been defined, Bayesian methods require that a sensor model or likelihood function for the sensor be established. In theory, this requires specification of a probability distribution $P(z | \mathbf{x}_{ij} = x_{ij})$ mapping each possible grid state x_{ij} to a distribution on

Fig. 35.2 Observation update for the full Bayes filter. Prior to observation, an observation model in the form of the conditional density $P(z_k | x_k)$ is established. For a fixed value of x_k , equal to x_1 or x_2 for example, a density function $P(z_k | x_k = x_1)$ or $P(z_k | x_k = x_2)$ is defined describing the likelihood of making the observation z_k . Together the density $P(z_k | x_k)$ is then a function of both z_k and x_k . This conditional density then defines the observation model. Now, in operation, a specific observation $z_k = x_1$ is made and the resulting distribution $P(z_k = x_1 | x_k)$ defines a density function (now termed the likelihood function) on x_k . This density is then multiplied by the prior density $P(x_k^-)$ and normalized to obtain the posterior distribution $P(x_k | z_k)$ describing knowledge in the state after observation

observations. Practically, however, this is implemented simply as another *observation* grid so that for a specific observation $z = z$ (taken from a specific location), a grid of likelihoods on the states x_{ij} is produced in the form $P(z = z | x_{ij}) = \Lambda(x_{ij})$. It is then trivial to apply Bayes' rule to update the property value at each grid cell as

$$P^+(x_{ij}) = C \Lambda(x_{ij}) P(x_{ij}), \quad \forall i, j, \quad (35.9)$$

where C is a normalizing constant obtained by summing posterior probabilities to one *at node ij only*. Computationally, this is a simple pointwise multiplication of two grids. Some care needs to be taken that the two grids appropriately overlap and align with each other at the right scale. In some instances it is also valuable to encode the fact that spatially adjacent cells will

influence each other; that is, if we knew the value of the property (occupancy, temperature, for example) at ij we will have some belief also of the value of this property at adjacent nodes $i+1, j$, $i, j+1$, etc. Different sensors and the fusion of different sensor outputs is accommodated simply by building appropriate sensor models $\Lambda(x_{ij})$.

Grids can also be used for tracking and self-tracking (localization). The state x_{ij} in this case is the location of the entity being tracked. This is a qualitatively different definition of state from that used in mapping. The probability $P(x_{ij})$ must now be interpreted as the probability that the object being tracked occupies the grid cell ij . In the case of mapping, the sum of property probabilities at each grid cell is one, whereas in the case of tracking, the

sum of location probabilities over *the whole grid* must sum to one. Otherwise, the procedure for updating is very similar. An observation grid is constructed which, when instantiated with an observation value, provides a location likelihood grid

$$P(z = z | \mathbf{x}_{ij}) = \Lambda(\mathbf{x}_{ij}) .$$

Bayes' rule is then applied to update the location probability at each grid cell in the same form as (35.9) except that now the normalization constant C is obtained by summing posterior probabilities over *all* ij grid cells. This can become computationally expensive, especially if the grid has three or more dimensions. One major advantage of grid-based tracking is that it is easy to incorporate quite complex prior information. For example, if it is known that the object being tracked is on a road, then the probability location values for all off-road grid cells can simply be set to zero.

Grid-based fusion is appropriate to situations where the domain size and dimension are modest. In such cases, grid-based methods provide straightforward and effective fusion algorithms. Grid-based methods can be extended in a number of ways; to hierarchical (quad-tree) grids, or to irregular (triangular, pentagonal) grids. These can help reduce computation in larger spaces. Monte Carlo and particle filtering methods (Sect. 35.1.4) may be considered as grid-based methods, where the grid cells themselves are sample of the underlying probability density for the state.

35.1.3 The Kalman Filter

The Kalman filter is a recursive linear estimator that successively calculates an estimate for a continuous valued state, that evolves over time, on the basis of periodic observations of the state. The Kalman filter employs an explicit statistical model of how the parameter of interest $\mathbf{x}(t)$ evolves over time and an explicit statistical model of how the observations $\mathbf{z}(t)$ that are made are related to this parameter. The gains employed in a Kalman filter are chosen to ensure that, with certain assumptions about the observation and process models used, the resulting estimate $\hat{\mathbf{x}}(t)$ minimizes mean-squared error and is thus the conditional mean $\hat{\mathbf{x}}(t) = E[\mathbf{x}(t) | \mathbf{Z}']$: an average, rather than a most likely value.

The Kalman filter has a number of features which make it ideally suited to dealing with complex multisensor estimation and data fusion problems. In particular, the explicit description of process and observations allows a wide variety of different sensor models to be incorporated within the basic algorithm. In addition, the consistent use of statistical measures of uncertainty makes it possible to quantitatively evaluate the role each

sensor plays in overall system performance. Further, the linear recursive nature of the algorithm ensures that its application is simple and efficient. For these reasons, the Kalman filter has found widespread application in many different data fusion problems [35.6–9].

In robotics, the Kalman filter is most suited to problems in tracking, localization, and navigation, and less so to problems in mapping. This is because the algorithm works best with well-defined state descriptions (positions, velocities, for example), and for states where observation and time-propagation models are also well understood.

Observation and Transition Models

The Kalman filter may be considered a specific instance of the recursive Bayesian filter of (35.7) and (35.8) for the case where the probability densities on states are Gaussian. The starting point for the Kalman Filter algorithm is to define a model for the states to be estimated in the standard state-space form

$$\dot{\mathbf{x}}(t) = \mathbf{F}(t)\mathbf{x}(t) + \mathbf{B}(t)\mathbf{u}(t) + \mathbf{G}(t)\mathbf{v}(t) , \quad (35.10)$$

where $\mathbf{x}(t)$ is the state vector of interest, $\mathbf{u}(t)$ is a known control input, $\mathbf{v}(t)$ is a random variable describing uncertainty in the evolution of the state, and $\mathbf{F}(t)$, $\mathbf{B}(t)$, and $\mathbf{G}(t)$ are matrices describing the contribution of states, controls, and noise to state transition [35.7]. An observation (output) model is also defined in standard state-space form

$$\mathbf{z}(t) = \mathbf{H}(t)\mathbf{x}(t) + \mathbf{D}(t)\mathbf{w}(t) , \quad (35.11)$$

where $\mathbf{z}(t)$ is the observation vector, $\mathbf{w}(t)$ is a random variable describing uncertainty in the observation, and where $\mathbf{H}(t)$ and $\mathbf{D}(t)$ are matrices describing the contribution of state and noise to the observation.

These equations define the evolution of a continuous-time system with continuous observations being made of the state. However, the Kalman Filter is almost always implemented in discrete time $t_k = k$. It is straightforward [35.8] to obtain a discrete-time version of (35.10) and (35.11) in the form

$$\mathbf{x}(k) = \mathbf{F}(k)\mathbf{x}(k-1) + \mathbf{B}(k)\mathbf{u}(k) + \mathbf{G}(k)\mathbf{v}(k) , \quad (35.12)$$

$$\mathbf{z}(k) = \mathbf{H}(k)\mathbf{x}(k) + \mathbf{D}(k)\mathbf{w}(k) . \quad (35.13)$$

A basic assumption in the derivation of the Kalman filter is that the random sequences $\mathbf{v}(k)$ and $\mathbf{w}(k)$ describing process and observation noise are all Gaussian, temporally uncorrelated, and zero-mean

$$E[\mathbf{v}(k)] = E[\mathbf{w}(k)] = \mathbf{0} , \quad \forall k , \quad (35.14)$$

with known covariance

$$\mathbf{E}[\mathbf{v}(i)\mathbf{v}^T(j)] = \delta_{ij}\mathbf{Q}(i), \quad \mathbf{E}[\mathbf{w}(i)\mathbf{w}^T(j)] = \delta_{ij}\mathbf{R}(i). \quad (35.15)$$

It is also generally assumed that the process and observation noises are also uncorrelated

$$\mathbf{E}[\mathbf{v}(i)\mathbf{w}^T(j)] = \mathbf{0}, \quad \forall i, j. \quad (35.16)$$

These are equivalent to a Markov property requiring observations and successive states to be conditionally independent. If the sequences $\mathbf{v}(k)$ and $\mathbf{w}(k)$ are temporally correlated, a shaping filter can be used to whiten the observations, again making the assumptions required for the Kalman filter valid [35.8]. If the process and observation noise sequences are correlated, then this correlation can also be accounted for in the Kalman filter algorithm [35.10]. If the sequence is not Gaussian, but is symmetric with finite moments, then the Kalman filter will still produce good estimates. If however, the sequence has a distribution which is skewed or otherwise pathological, results produced by the Kalman filter will be misleading and there will be a good case for using a more-sophisticated Bayesian filter [35.5].

Filtering Algorithm

The Kalman filter algorithm produces estimates that minimize mean-squared estimation error conditioned on a given observation sequence and so is the conditional mean

$$\hat{\mathbf{x}}(i|j) \triangleq \mathbf{E}[\mathbf{x}(i) | \mathbf{z}(1), \dots, \mathbf{z}(j)] \triangleq \mathbf{E}[\mathbf{x}(i) | \mathbf{Z}^j]. \quad (35.17)$$

The estimate variance is defined as the mean-squared error in this estimate

$$\mathbf{P}(i|j) \triangleq \mathbf{E}\{[\mathbf{x}(i) - \hat{\mathbf{x}}(i|j)][\mathbf{x}(i) - \hat{\mathbf{x}}(i|j)]^T | \mathbf{Z}^j\}. \quad (35.18)$$

The estimate of the state at a time k given all information up to time k is written $\hat{\mathbf{x}}(k|k)$. The estimate of the state at a time k given only information up to time $k-1$ is called a one-step-ahead prediction (or just a prediction) and is written $\hat{\mathbf{x}}(k|k-1)$.

The Kalman filter algorithm is now stated without proof. Detailed derivations can be found in many books on the subject, for example [35.7, 8]. The state is assumed to evolve in time according to (35.12). Observations of this state are made at regular time intervals according to (35.13). The noise processes entering the system are assumed to obey (35.14–35.16). It is also

assumed that an estimate $\hat{\mathbf{x}}(k-1|k-1)$ of the state $\mathbf{x}(k-1)$ at time $k-1$ based on all observations made up to and including time $k-1$ is available, and that this estimate is equal to the conditional mean of the true state $\mathbf{x}(k-1)$ conditioned on these observations. The conditional variance $\mathbf{P}(k-1|k-1)$ in this estimate is also assumed known. The Kalman filter then proceeds recursively in two stages (Fig. 35.3).

Prediction. A prediction $\hat{\mathbf{x}}(k|k-1)$ of the state at time k and its covariance $\mathbf{P}(k|k-1)$ is computed according to

$$\hat{\mathbf{x}}(k|k-1) = \mathbf{F}(k)\hat{\mathbf{x}}(k-1|k-1) + \mathbf{B}(k)\mathbf{u}(k), \quad (35.19)$$

$$\mathbf{P}(k|k-1) = \mathbf{F}(k)\mathbf{P}(k-1|k-1)\mathbf{F}^T(k) + \mathbf{G}(k)\mathbf{Q}(k)\mathbf{G}^T(k). \quad (35.20)$$

Update. At time k an observation $\mathbf{z}(k)$ is made and the updated estimate $\hat{\mathbf{x}}(k|k)$ of the state $\mathbf{x}(k)$, together with the updated estimate covariance $\mathbf{P}(k|k)$, is computed from the state prediction and observation according to

$$\hat{\mathbf{x}}(k|k) = \hat{\mathbf{x}}(k|k-1) + \mathbf{W}(k)[\mathbf{z}(k) - \mathbf{H}(k)\hat{\mathbf{x}}(k|k-1)], \quad (35.21)$$

$$\mathbf{P}(k|k) = \mathbf{P}(k|k-1) - \mathbf{W}(k)\mathbf{S}(k)\mathbf{W}^T(k), \quad (35.22)$$

where the gain matrix $\mathbf{W}(k)$ is given by

$$\mathbf{W}(k) = \mathbf{P}(k|k-1)\mathbf{H}(k)\mathbf{S}^{-1}(k), \quad (35.23)$$

where

$$\mathbf{S}(k) = \mathbf{R}(k) + \mathbf{H}(k)\mathbf{P}(k|k-1)\mathbf{H}(k) \quad (35.24)$$

is the innovation covariance. The difference between the observation $\mathbf{z}(k)$ and the predicted observation $\mathbf{H}(k)\hat{\mathbf{x}}(k|k-1)$ is termed the *innovation* or residual $\mathbf{v}(k)$

$$\mathbf{v}(k) = \mathbf{z}(k) - \mathbf{H}(k)\hat{\mathbf{x}}(k|k-1). \quad (35.25)$$

The innovation is an important measure of the deviation between the filter estimates and the observation sequence. Indeed, because the true states are not usually available for comparison with the estimated states, the innovation is often the only measure of how well the estimator is performing. The innovation is particularly important in data association.

The Extended Kalman Filter

The extended Kalman filter (EKF) is a form of the Kalman filter that can be employed when the state model and/or the observation model are nonlinear. The EKF is briefly described in this section.

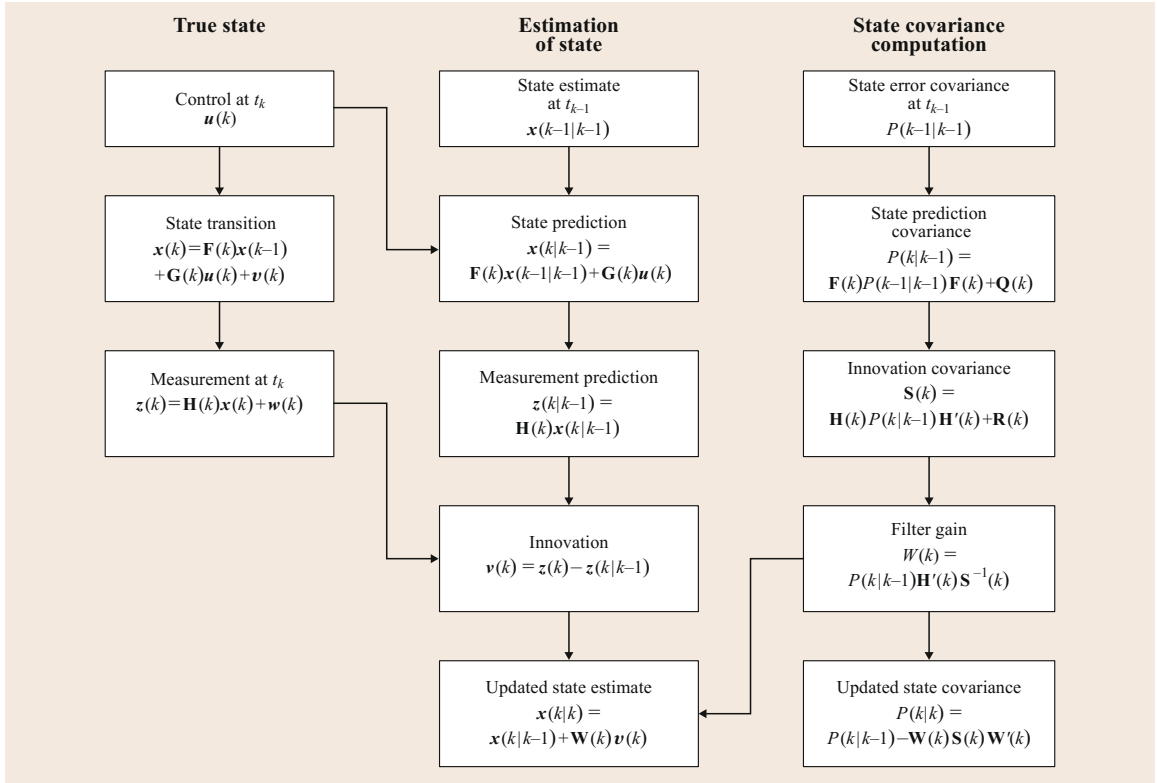

Fig. 35.3 Block diagram of the Kalman filter cycle (after Bar-Shalom and Fortmann [35.7])

The state models considered by the **EKF** are described in state-space notation by a first-order nonlinear vector differential equation or state model of the form

$$\dot{\mathbf{x}}(t) = \mathbf{f}[\mathbf{x}(t), \mathbf{u}(t), \mathbf{v}(t), t], \quad (35.26)$$

where $\mathbf{f}[\cdot, \cdot, \cdot, \cdot]$ is now a general nonlinear mapping of state and control input to state transition. The observation models considered by the **EKF** are described in state-space notation by a nonlinear vector function in the form

$$\mathbf{z}(t) = \mathbf{h}[\mathbf{x}(t), \mathbf{u}(t), \mathbf{w}(t), t], \quad (35.27)$$

where $\mathbf{h}[\cdot, \cdot, \cdot, \cdot]$ is now a general nonlinear mapping of state and control input to observations.

The **EKF**, like the Kalman filter, is almost always implemented in discrete time. By integration and with appropriate identification of discrete time states and observations, the state model is written

$$\mathbf{x}(k) = \mathbf{f}[\mathbf{x}(k-1), \mathbf{u}(k), \mathbf{v}(k), k], \quad (35.28)$$

and the observation model as

$$\mathbf{z}(k) = \mathbf{h}[\mathbf{x}(k), \mathbf{w}(k)]. \quad (35.29)$$

Like the Kalman filter, it is assumed that the noises $\mathbf{v}(k)$ and $\mathbf{w}(k)$ are all Gaussian, temporally uncorrelated,

and zero-mean with known variance as defined in (35.14–35.16). The **EKF** aims to minimize the mean-squared error and thereby compute an approximation to the conditional mean. It is assumed therefore that an estimate of the state at time $k-1$ is available which is approximately equal to the conditional mean, $\hat{\mathbf{x}}(k-1 | k-1) \approx \mathbf{E}[\mathbf{x}(k-1) | \mathbf{Z}^{k-1}]$. The **EKF** algorithm will now be stated without proof. Detailed derivations may be found in any number of books on the subject. The principle stages in the derivation of the **EKF** follow directly from those of the linear Kalman filter with the additional step that the process and observation models are linearized as a Taylor series about the estimate and prediction, respectively. The algorithm has two stages: prediction and update.

Prediction. A prediction $\hat{\mathbf{x}}(k | k-1)$ of the state at time k and its covariance $\mathbf{P}(k | k-1)$ is computed according to

$$\hat{\mathbf{x}}(k | k-1) = \mathbf{f}[\hat{\mathbf{x}}(k-1 | k-1), \mathbf{u}(k)], \quad (35.30)$$

$$\mathbf{P}(k | k-1) = \nabla \mathbf{f}_{\mathbf{x}}(k) \mathbf{P}(k-1 | k-1) \nabla^T \mathbf{f}_{\mathbf{x}}(k) + \nabla \mathbf{f}_{\mathbf{v}}(k) \mathbf{Q}(k) \nabla^T \mathbf{f}_{\mathbf{v}}(k). \quad (35.31)$$

Update. At time k an observation $z(k)$ is made and the updated estimate $\hat{\mathbf{x}}(k | k)$ of the state $\mathbf{x}(k)$, together with the updated estimate covariance $\mathbf{P}(k | k)$ is computed from the state prediction and observation according to

$$\hat{\mathbf{x}}(k | k) = \hat{\mathbf{x}}(k | k-1) + \mathbf{W}(k)\{z(k) - \mathbf{h}[\hat{\mathbf{x}}(k | k-1)]\}, \quad (35.32)$$

$$\mathbf{P}(k | k) = \mathbf{P}(k | k-1) - \mathbf{W}(k)\mathbf{S}(k)\mathbf{W}^T(k), \quad (35.33)$$

where

$$\mathbf{W}(k) = \mathbf{P}(k | k-1)\nabla^T \mathbf{h}_x(k)\mathbf{S}^{-1}(k), \quad (35.34)$$

and

$$\begin{aligned} \mathbf{S}(k) &= \nabla \mathbf{h}_w(k)\mathbf{R}(k)\nabla^T \mathbf{h}_w(k) \\ &+ \nabla \mathbf{h}_x(k)\mathbf{P}(k | k-1)\nabla^T \mathbf{h}_x(k), \end{aligned} \quad (35.35)$$

and where the Jacobian $\nabla \mathbf{f}_x(k)$ is evaluated at $\mathbf{x}(k-1) = \hat{\mathbf{x}}(k-1 | k-1)$ and $\nabla \mathbf{h}_x(k)$ is evaluated at $\mathbf{x}(k) = \hat{\mathbf{x}}(k | k-1)$.

A comparison of (35.19–35.24) with (35.30–35.35) makes it clear that the EKF algorithm is very similar to the linear Kalman filter algorithm, with the substitutions $\mathbf{F}(k) \rightarrow \nabla \mathbf{f}_x(k)$ and $\mathbf{H}(k) \rightarrow \nabla \mathbf{h}_x(k)$ being made in the equations for the variance and gain propagation. Thus, the EKF is, in effect, a linear estimator for a state error which is described by a *linear* equation and which is being observed according to a *linear* equation of the form of (35.13).

The EKF works in much the same way as the linear Kalman filter with some notable caveats:

- The Jacobians $\nabla \mathbf{f}_x(k)$ and $\nabla \mathbf{h}_x(k)$ are typically not constant, being functions of both state and time step. This means that unlike the linear filter, the covariances and gain matrix must be computed online as estimates and predictions are made available, and will not in general tend to constant values. This significantly increases the amount of computation which must be performed online by the algorithm.
- As the linearized model is derived by perturbing the true state and observation models around a predicted or nominal trajectory, great care must be taken to ensure that these predictions are always close enough to the true state that second order terms in the linearization are indeed insignificant. If the nominal trajectory is too far away from the true trajectory then the true covariance will be much larger than the estimated covariance and the filter will become poorly matched. In extreme cases the filter may also become unstable.
- The EKF employs a linearized model that must be computed from an approximate knowledge of the

state. Unlike the linear algorithm this means that the filter must be accurately initialized at the start of operation to ensure that the linearized models obtained are valid. If this is not done, the estimates computed by the filter will simply be meaningless.

The Information Filter

The information filter is mathematically equivalent to a Kalman filter. However, rather than generating state estimates $\hat{\mathbf{x}}(i | j)$ and covariances $\mathbf{P}(i | j)$ it uses information state variables $\hat{\mathbf{y}}(i | j)$ and information matrices $\mathbf{Y}(i | j)$, which are related to each other through the relationships

$$\begin{aligned} \hat{\mathbf{y}}(i | j) &= \mathbf{P}^{-1}(i | j)\hat{\mathbf{x}}(i | j), \\ \mathbf{Y}(i | j) &= \mathbf{P}^{-1}(i | j). \end{aligned} \quad (35.36)$$

The information filter has the same prediction–update structure as the Kalman filter.

Prediction. A prediction $\hat{\mathbf{y}}(k | k-1)$ of the information state at time k and its information matrix $\mathbf{Y}(k | k-1)$ is computed according to (Joseph form [35.8])

$$\begin{aligned} \hat{\mathbf{y}}(k | k-1) &= (\mathbf{I} - \mathbf{\Omega}\mathbf{G}^T)\mathbf{F}^{-T}\hat{\mathbf{y}}(k-1 | k-1) \\ &+ \mathbf{Y}(k | k-1)\mathbf{B}\mathbf{u}(k), \end{aligned} \quad (35.37)$$

$$\mathbf{Y}(k | k-1) = \mathbf{M}(k) - \mathbf{\Omega}\mathbf{\Sigma}\mathbf{\Omega}^T, \quad (35.38)$$

respectively, where

$$\begin{aligned} \mathbf{M}(k) &= \mathbf{F}^{-T}\mathbf{Y}(k-1 | k-1)\mathbf{F}^{-1}, \\ \mathbf{\Sigma} &= \mathbf{G}^T\mathbf{M}(k)\mathbf{G} + \mathbf{Q}^{-1}, \end{aligned}$$

and

$$\mathbf{\Omega} = \mathbf{M}(t_k)\mathbf{G}\mathbf{\Sigma}^{-1}.$$

It should be noted that $\mathbf{\Sigma}$, whose inverse is required to compute $\mathbf{\Omega}$, has the same dimensionality as the process driving noise, which is normally considerably smaller than the state dimension. Further, the matrix \mathbf{F}^{-1} is the state-transition matrix evaluated backwards in time and so must always exist.

Update. At time k an observation $z(k)$ is made and the updated information state estimate $\hat{\mathbf{y}}(k | k)$ together with the updated information matrix $\mathbf{Y}(k | k)$ is computed from

$$\hat{\mathbf{y}}(k | k) = \hat{\mathbf{y}}(k | k-1) + \mathbf{H}(k)\mathbf{R}^{-1}(k)z(k), \quad (35.39)$$

$$\mathbf{Y}(k | k) = \mathbf{Y}(k | k-1) + \mathbf{H}(k)\mathbf{R}^{-1}(k)\mathbf{H}^T(k). \quad (35.40)$$

We emphasize that (35.38) and (35.37) are mathematically identical to (35.19) and (35.20), and that (35.39) and (35.40) are mathematically identical to (35.21) and (35.22). It will be noted that there is a duality between information and state space forms [35.10]. This duality is evident from the fact that $\mathbf{\Omega}$ and $\mathbf{\Sigma}$ in the prediction stage of the information filter play an equivalent role to the gain matrix \mathbf{W} and innovation covariance \mathbf{S} in the update stage of the Kalman filter. Furthermore, the simple linear update step for the information filter is mirrored in the simple linear prediction step for the Kalman filter.

The main advantage of the information filter over the Kalman filter in data fusion problems is the relative simplicity of the update stage. For a system with n sensors, the fused information state update is *exactly* the linear sum of information contributions from all sensors as

$$\begin{aligned}\hat{\mathbf{y}}(k|k) &= \hat{\mathbf{y}}(k|k-1) + \sum_{i=1}^n \mathbf{H}_i(k) \mathbf{R}_i^{-1}(k) \mathbf{z}_i(k), \\ \mathbf{Y}(k|k) &= \mathbf{Y}(k|k-1) + \sum_{i=1}^n \mathbf{H}_i(k) \mathbf{R}_i^{-1}(k) \mathbf{H}_i^T(k).\end{aligned}\quad (35.41)$$

The reason such an expression exists in this form is that the information filter is essentially a log-likelihood expression of Bayes' rule, where products of likelihoods (35.4) are turned into sums. No such simple expression for multisensor updates exists for the Kalman filter. This property of the information filter has been exploited for data fusion in robotic networks [35.11, 12] and more recently in robot navigation and localization problems [35.1]. One substantial disadvantage of the information filter is the coding of nonlinear models, especially for the prediction step.

When to Use a Kalman or Information Filter

Kalman or information filters are appropriate to data fusion problems where the entity of interest is well defined by a continuous parametric state. This would include estimation of the position, attitude, and velocity of a robot or other object, or the tracking of a simple geometric feature such as a point, line or curve. Kalman and information filters are inappropriate for estimating properties such as spatial occupancy, discrete labels, or processes whose error characteristics are not easily parameterized.

35.1.4 Sequential Monte Carlo Methods

Monte Carlo (MC) filter methods describe probability distributions as a set of weighted samples of an underlying

ing state space. MC filtering then uses these samples to simulate probabilistic inference usually through Bayes' rule. Many samples or simulations are performed. By studying the statistics of these samples as they progress through the inference process, a probabilistic picture of the process being simulated can be built up.

Representing Probability Distributions

In sequential Monte Carlo methods, probability distributions are described in terms of a set of support points (state-space values) \mathbf{x}^i , $i = 1, \dots, N$, together with a corresponding set of normalized weights w^i , $i = 1, \dots, N$, where $\sum_i w^i = 1$. The support points and weights can be used to define a probability density function in the form

$$P(\mathbf{x}) \approx \sum_{i=1}^N w^i \delta(\mathbf{x} - \mathbf{x}^i). \quad (35.42)$$

A key question is how these support points and weights are selected to obtain a faithful representation of the probability density $P(\mathbf{x})$. The most general way of selecting support values is to use an *importance density* $q(\mathbf{x})$. The support values \mathbf{x}^i are drawn as samples from this density; where the density has high probability, more support values are chosen, and where the density has low probability, few support support vectors are selected. The weights in (35.42) are then computed from

$$w^i \propto \frac{P(\mathbf{x}^i)}{q(\mathbf{x}^i)}. \quad (35.43)$$

Practically, a sample \mathbf{x}^i is drawn from the importance distribution. The sample is then instantiated in the underlying probability distribution to yield the value $P(\mathbf{x} = \mathbf{x}^i)$. The ratio of the two probability values, appropriately normalized, then becomes the weight.

There are two instructive extremes of the importance sampling method:

1. At one extreme, the importance density could be taken to be a uniform distribution, so the support values \mathbf{x}^i are uniformly distributed on the state space in a close approximation to a grid. The probabilities $q(\mathbf{x}^i)$ are also therefore equal. The weights computed from (35.43) are then simply proportional to the probabilities $w^i \propto P(\mathbf{x} = \mathbf{x}^i)$. The result is a model for the distribution which looks very like the regular grid model.
2. At the other extreme, we could choose an importance density equal to the probability model $q(\mathbf{x}) = P(\mathbf{x})$. Samples of the support values \mathbf{x}^i are now drawn from this density. Where the density is high

there will be many samples, where the density is low there will be few samples. However, if we substitute $q(\mathbf{x}^i) = P(\mathbf{x}^i)$ into (35.43), it is clear that the weights all become equal $w^i = \frac{1}{N}$. A set of samples with equal weights is known as a *particle* distribution.

It is, of course, possible to mix these two representations to describe a probability distribution both in terms of a set of weights and in terms of a set of support values. The complete set of samples and weights describing a probability distribution $\{\mathbf{x}^i, w^i\}_{i=1}^N$ is termed a *random measure*.

The Sequential Monte Carlo Method

Sequential Monte Carlo (SMC) filtering is a simulation of the recursive Bayes update equations using sample support values and weights to describe the underlying probability distributions.

The starting point is the recursive or sequential Bayes observation update given in (35.7) and (35.8). The SMC recursion begins with an a posteriori probability density represented by a set of support values and weights $\{\mathbf{x}_{k-1}^i, w_{k-1|k-1}^i\}_{i=1}^{N_{k-1}}$ in the form

$$P(\mathbf{x}_{k-1} | \mathbf{Z}^{k-1}) = \sum_{i=1}^{N_{k-1}} w_{k-1}^i \delta(\mathbf{x}_{k-1} - \mathbf{x}_{k-1}^i) . \quad (35.44)$$

The prediction step requires that (35.44) is substituted into (35.8) where the joint density is marginalized. Practically however, this complex step is avoided by implicitly assuming that the importance density is exactly the transition model as

$$q_k(\mathbf{x}_k^i) = P(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i) . \quad (35.45)$$

This allows new support values \mathbf{x}_k^i to be drawn on the basis of old support values \mathbf{x}_{k-1}^i while leaving the weights unchanged $w_k^i = w_{k-1}^i$. With this, the prediction becomes

$$P(\mathbf{x}_k | \mathbf{Z}^{k-1}) = \sum_{i=1}^{N_k} w_{k-1}^i \delta(\mathbf{x}_k - \mathbf{x}_k^i) . \quad (35.46)$$

The SMC observation update step is relatively straightforward. An observation model $P(z_k | \mathbf{x}_k)$ is defined. This is a function on both variables, z_k and \mathbf{x}_k , and is a probability distribution on z_k (integrates to unity). When an observation or measurement is made, $z_k = z_k$, the observation model becomes a function of state \mathbf{x}_k only. If samples of the state are taken $\mathbf{x}_k = \mathbf{x}_k^i$, $i =$

$1, \dots, N_k$, the observation model $P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i)$ becomes a set of scalars describing the likelihood that the sample \mathbf{x}_k^i could have given rise to the observation z_k . Substituting these likelihoods and (35.46) into (35.7) gives

$$\begin{aligned} P(\mathbf{x}_k | \mathbf{Z}^k) \\ = C \sum_{i=1}^{N_k} w_{k-1}^i P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i) \delta(\mathbf{x}_k - \mathbf{x}_k^i) . \end{aligned} \quad (35.47)$$

This is normally implemented in the form of an updated set of normalized weights

$$w_k^i = \frac{w_{k-1}^i P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i)}{\sum_{j=1}^{N_k} w_{k-1}^j P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^j)} , \quad (35.48)$$

and so

$$P(\mathbf{x}_k | \mathbf{Z}^k) = \sum_{i=1}^{N_k} w_k^i \delta(\mathbf{x}_k - \mathbf{x}_k^i) . \quad (35.49)$$

Note that the support values in (35.49) are the same as those in (35.46), only the weights have been changed by the observation update.

The implementation of the SMC method requires the enumeration of models for both the state transition $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ and the observation $P(z_k | \mathbf{x}_k)$. These need to be presented in a form that allows instantiation of values for z_k , \mathbf{x}_k , and \mathbf{x}_{k-1} . For low-dimensional state spaces, interpolation in a lookup table is a viable representation. For high-dimensional state spaces, the preferred method is to provide a representation in terms of a function.

Practically, (35.46) and (35.49) are implemented as follows.

Time Update. A process model is defined in the usual state-space form as $\mathbf{x}_k = \mathbf{f}(\mathbf{x}_{k-1}, \mathbf{w}_{k-1}, k)$, where \mathbf{w}_k is an independent noise sequence with known probability density $P(\mathbf{w}_k)$. The prediction step is now implemented as follows: N_k samples \mathbf{w}_k^i , $i = 1, \dots, N_k$ are drawn from the distribution $P(\mathbf{w}_k)$. The N_k support values \mathbf{x}_{k-1}^i together with the samples \mathbf{w}_k^i are passed through the process model as

$$\mathbf{x}_k^i = \mathbf{f}(\mathbf{x}_{k-1}^i, \mathbf{w}_{k-1}^i, k) , \quad (35.50)$$

yielding a new set of support vectors \mathbf{x}_k^i . The weights for these support vectors w_{k-1}^i are not changed. In effect, the process model is simply used to do N_k simulations of state propagation.

Observation Update. The observation model is also defined in the usual state-space form as $z_k = \mathbf{h}(\mathbf{x}_k, \mathbf{v}_k, k)$, where \mathbf{v}_k is an independent noise sequence with known probability density $P(\mathbf{v}_k)$. The observation step is now implemented as follows. A measurement $z_k = z_k$ is made. For each support value \mathbf{x}_k^i , a likelihood is computed as

$$\Lambda(\mathbf{x}_k^i) = P(z_k = z_k | \mathbf{x}_k = \mathbf{x}_k^i) . \quad (35.51)$$

Practically, this requires that the observation model be in an equational form (such as a Gaussian) which allows computation of the likelihood in the error between the measured value z_k and the observations predicted by each particle $\mathbf{h}(\mathbf{x}_k^i, k)$. The updated weights after observation are just

$$w_k^i \propto w_{k-1}^i P(z_k = z_k | \mathbf{x}_k^i) . \quad (35.52)$$

Resampling

After the weights are updated it is usual to resample the measure $\{\mathbf{x}_k^i, w_k^i\}_{i=1}^N$. This focuses the samples in on those areas that have most probability density. The decision to resample is made on the basis of the *effective number*, N_{eff} of particles in the sample, approximately estimated from

$$N_{\text{eff}} = \frac{1}{\sum_i (w_k^i)^2} .$$

The sampling importance resampling (SIR) algorithm resamples at every cycle so that the weights are always equal. One of the key problems with resampling is that the sample set fixates on a few highly likely samples. This problem of fixating on a few highly likely particles during resampling is known as *sample impoverishment*. Generally, it is good to resample when N_{eff} falls to some fraction of the actual samples (say $1/2$).

When to Use Monte Carlo Methods

Monte Carlo (MC) methods are well suited to problems where state-transition models and observation models are highly nonlinear. This is because sample-based methods can represent very general probability densities. In particular multimodal or multiple hypothesis density functions are well handled by Monte Carlo techniques. One caveat to note however is that the models $P(\mathbf{x}_k | \mathbf{x}_{k-1})$ and $P(z_k | \mathbf{x}_k)$ must be enumerable in all cases and must typically be in a simple parametric form. MC methods also span the gap between parametric and grid-based data fusion methods.

Monte Carlo methods are inappropriate for problems where the state space is of high dimension. In general the number of samples required to faithfully

model a given density increases exponentially with state-space dimension. The effects of dimensionality can be limited by marginalizing out states that can be modeled without sampling, a procedure known as Rao–Blackwellization.

35.1.5 Alternatives to Probability

The representation of uncertainty is so important to the problem of information fusion that a number of alternative modeling techniques have been proposed to deal with perceived limitations in probabilistic methods.

There are three main perceived limitations of probabilistic modeling techniques:

1. Complexity: the need to specify a large number of probabilities to be able to apply probabilistic reasoning methods correctly.
2. Inconsistency: the difficulties involved in specifying a consistent set of beliefs in terms of probability and using these to obtain consistent deductions about states of interest.
3. Precision of models: the need to be precise in the specification of probabilities for quantities about which little is known.
4. Uncertainty about uncertainty: the difficulty in assigning probability in the face of uncertainty, or ignorance about the source of information.

There are three main techniques put forward to address these issues: interval calculus, fuzzy logic, and the theory of evidence (Dempster–Shafer methods). We briefly discuss each of these in turn.

Interval Calculus

The representation of uncertainty using an interval to bound true parameter values has a number of potential advantages over probabilistic techniques. In particular, intervals provide a good measure of uncertainty in situations where there is a lack of probabilistic information, but in which sensor and parameter error is known to be bounded. In interval techniques, the uncertainty in a parameter x is simply described by a statement that the true value of the state x is known to be bounded from below by a , and from above by b ; $x \in [a, b]$. It is important that no other additional probabilistic structure is implied; in particular the statement $x \in [a, b]$ does not necessarily imply that x is equally probable (uniformly distributed) over the interval $[a, b]$.

There are a number of simple and basic rules for the manipulation of interval errors. These are described in detail in the book by Moore [35.13] (whose analysis was originally aimed at understanding limited-precision computer arithmetic). Briefly, with $a, b, c, d \in \mathbb{R}$, addi-

tion, subtraction, multiplication, and division are defined by the following algebraic relations

$$\begin{aligned} [a, b] + [c, d] &= [a + c, b + d], \\ [a, b] - [c, d] &= [a - d, b - c], \end{aligned} \quad (35.53)$$

$$[a, b] \times [c, d] = [\min(ac, ad, bc, bd), \max(ac, ad, bc, bd)], \quad (35.54)$$

$$\frac{[a, b]}{[c, d]} = [a, b] \times \left[\frac{1}{d}, \frac{1}{c} \right], \quad 0 \notin [c, d]. \quad (35.55)$$

It can be shown that interval addition and multiplication are both associative and commutative. Interval arithmetic admits an obvious metric distance measure

$$d([a, b], [c, d]) = \max(|a - c|, |b - d|). \quad (35.56)$$

Matrix arithmetic using intervals is also possible, but substantially more complex, particularly when matrix inversion is required.

Interval calculus methods are sometimes used for detection. However, they are not generally used in data fusion problems since:

1. It is difficult to get results that converge to anything of value (it is too pessimistic), and
2. It is hard to encode dependencies between variables which are at the core of many data fusion problems.

Fuzzy Logic

Fuzzy logic has found widespread popularity as a method for representing uncertainty particularly in applications such as supervisory control and high-level data fusion tasks. It is often claimed that fuzzy logic provides an ideal tool for inexact reasoning, particularly in rule-based systems. Certainly, fuzzy logic has had some notable success in practical application.

A great deal has been written about fuzzy sets and fuzzy logic (e.g. [35.14] and the discussion in [35.15, Chap. 11]). Here we briefly describe the main definitions and operations without any attempt to consider the more advanced features of fuzzy-logic methods.

Consider a universal set consisting of the elements x ; $X = \{x\}$. Consider a proper subset $\mathcal{A} \subseteq X$ such that

$$\mathcal{A} = \{x \mid x \text{ has some specific property}\}.$$

In conventional logic systems, we can define a membership function $\mu_A(x)$ (also called the *characteristic function* which reports if a specific element $x \in X$ is

a member of this set

$$\mathcal{A} \Rightarrow \mu_A(x) = \begin{cases} 1 & \text{if } x \in \mathcal{A} \\ 0 & \text{if } x \notin \mathcal{A} \end{cases}.$$

For example X may be the set of all aircraft. The set \mathcal{A} may be the set of all supersonic aircraft. In the fuzzy logic literature, this is known as a *crisp* set. In contrast, a fuzzy set is one in which there is a *degree of membership*, ranging between 0 and 1. A fuzzy membership function $\mu_A(x)$ then defines the degree of membership of an element $x \in X$ to the set \mathcal{A} . For example, if X is again the set of all aircraft, \mathcal{A} may be the set of all *fast* aircraft. Then the fuzzy membership function $\mu_A(x)$ assigns a value between 0 and 1 indicating the degree of membership of every aircraft x to this set. Formally

$$\mathcal{A} \Rightarrow \mu_A \mapsto [0, 1].$$

Composition rules for fuzzy sets follow the composition processes for normal crisp sets, for example,

$$\mathcal{A} \cap \mathcal{B} \Rightarrow \mu_{\mathcal{A} \cap \mathcal{B}}(x) = \min[\mu_A(x), \mu_B(x)],$$

$$\mathcal{A} \cup \mathcal{B} \Rightarrow \mu_{\mathcal{A} \cup \mathcal{B}}(x) = \max[\mu_A(x), \mu_B(x)].$$

The normal properties associated with binary logic now hold: commutativity, associativity, idempotence, distributivity, De Morgan's law, and absorption. The only exception is that the law of the excluded middle is no longer true

$$\mathcal{A} \cup \overline{\mathcal{A}} \neq X, \quad \mathcal{A} \cap \overline{\mathcal{A}} \neq \emptyset.$$

Together these definitions and laws provide a systematic means of reasoning about inexact values.

The relationship between fuzzy set theory and probability is still hotly debated.

Evidential Reasoning

Evidential reasoning (often called the Dempster-Shafer theory of evidence after the originators of these ideas) has seen intermittent success particularly in automated reasoning applications. Evidential reasoning is qualitatively different from either probabilistic methods or fuzzy set theory in the following sense. Consider a universal set X . In probability theory or fuzzy set theory, a belief mass may be placed on any element $x_i \in X$ and indeed on any subset $\mathcal{A} \subseteq X$. In evidential reasoning, belief mass can not only be placed on elements and sets, but also sets of sets. Specifically, while the domain of probabilistic methods is all possible subsets X , the domain of evidential reasoning is the power set 2^X .

As an example, consider the mutually exclusive set $X = \{\text{occupied}, \text{empty}\}$. In probability theory we

might assign a probability to each possible event, for example, $P(\text{occupied}) = 0.3$, and thus $P(\text{empty}) = 0.7$. In evidential reasoning, we construct the set of all subsets

$$2^{\mathcal{X}} = \{\{\text{occupied}, \text{empty}\}, \{\text{occupied}\}, \{\text{empty}\}, \emptyset\},$$

and belief mass is assigned to all elements of this set as

$$\begin{aligned} m(\{\text{occupied}, \text{empty}\}) &= 0.5, \\ m(\{\text{occupied}\}) &= 0.3, \\ m(\{\text{empty}\}) &= 0.2, \\ m(\emptyset) &= 0.0, \end{aligned}$$

(the null set \emptyset is assigned a belief mass of zero for normalization purposes). The interpretation of this is that there is a 30% chance of occupied, a 20% chance of empty, and a 50% chance of either occupied or empty. In effect, the measure placed on the set containing both occupied and empty is a measure of ignorance or inability to distinguish between the two alternatives. See [35.16] for a more-detailed example of applying the evidential method to certainty-grid navigation.

Evidential reasoning thus provides a method of capturing ignorance or an inability to distinguish between

alternatives. In probability theory, this would be dealt with in a very different manner by assigning an equal or uniform probability to each alternative. Yet, stating that there is a 50% chance of occupancy is clearly *not* the same as saying that it is unknown whether it will be occupied or not. The use of the power set as the *frame of discernment* allows a far richer representation of beliefs. However, this comes at the cost of a substantial increase in complexity. If there are n elements in the original set \mathcal{X} , then there will be 2^n possible subsets on which a belief mass will be assigned. For large n , this is clearly intractable. Further, when the set is continuous, the set of all subsets is not even measurable.

Evidential reasoning methods provide a means of assigning, and combining belief masses on sets. Methods also exist for obtaining related measures called *support* and *plausibility* which, in effect, provide upper and lower probability bounds in agreement with Dempster's original formulation of this method.

Evidential reasoning can play an important role in discrete data fusion systems, particularly in areas such as attribute fusion and situation assessment, where information may be unknown or ambiguous. Its use in lower-level data fusion problems is challenging as the assignment of belief mass to the power set scales exponentially with state cardinality.

35.2 Multisensor Fusion Architectures

The multisensor fusion methods described in the previous section provide the algorithmic means by which sensor data and their associated uncertainty models can be used to construct either implicit or explicit models of the environment. However, a multisensor fusion system must include many other functional components to manage and control the fusion process. The organization of these is termed a *multisensor fusion architecture*.

35.2.1 Architectural Taxonomy

Multisensor systems architectures can be organized in various ways. The military community has developed a layout of functional architectures based on the joint directors of the laboratories (JDL) model for multisensor systems. This approach views multisensor fusion in terms of signal, feature, threat and situation analysis levels (so-called JDL levels). The assessment of such systems is specified in terms of tracking performance, survivability, efficiency and bandwidth. Such measures are not generally appropriate in robotics applications and so the JDL model is not discussed this

further here (see [35.17, 18] for details). Other classification schemes distinguish between low- and high-level fusion [35.19], or centralized versus decentralized processing or data versus variable [35.20].

A general architectural framework for multisensor robotic systems has been developed and described in detail by Makarenko [35.21], and we will base our discussion on this approach. A system architecture is defined as follows.

Meta-Architecture

A set of high-level considerations that strongly characterize the system structure. The selection and organization of the system elements may be guided by aesthetics, efficiency, or other design criteria and goals (for example, system and component comprehensibility, modularity, scalability, portability, interoperability, (de)centralization, robustness, fault tolerance).

Algorithmic Architecture

A specific set of information fusion and decision-making methods. These methods address data heterogeneity, registration, calibration, consistency, informa-

tion content, independence, time interval and scale, and relationships between models and uncertainty.

Conceptual Architecture

The granularity and functional roles of components (specifically, mappings from algorithmic elements to functional structures).

Logical Architecture

Detailed canonical component types (i.e., object-oriented specifications) and interfaces to formalize intercomponent services. Components may be ad hoc or regimented, and other concerns include granularity, modularity, reuse, verification, data structures, semantics, etc. Communication issues include hierarchical versus heterarchical organization, shared memory versus message passing, information-based characterizations of subcomponent interactions, pull/push mechanisms, subscribe-publish mechanisms, etc. Control involves both the control of actuation systems within the multisensor fusion system, as well as control of information requests and dissemination within the system, and any external control decisions and commands.

Execution Architecture

Defines mapping of components to execution elements. This includes internal or external methods of ensuring correctness of the code (i.e., that the environment and sensor models have been correctly transformed from mathematical or other formal descriptions into computer implementations), and also validation of the models (i.e., ensure that the formal descriptions match physical reality to the required extent).

In any closed-loop control system, sensors are used to provide the feedback information describing the current status of the system and its uncertainties. Building a sensor system for a given application is a system engineering process that includes the analysis of system requirements, a model of the environment, the determination of system behavior under different conditions, and the selection of suitable sensors [35.22]. The next step in building the sensor system is to assemble the hardware components and develop the necessary software modules for data fusion and interpretation. Finally, the system is tested, and the performance is analyzed. Once the system is built, it is necessary to monitor the different components of the system for the purpose of testing, debugging, and analysis. The system also requires quantitative measures in terms of time complexity, space complexity, robustness, and efficiency.

In addition, designing and implementing real-time systems are becoming increasingly complex owing to many added features such as graphical user interfaces

(GUIs), visualization capabilities, and the use of many sensors of different types. Therefore, many software engineering issues such as reusability and the use of commercial off-the-shelf (COTS) components [35.23], real-time issues [35.24–26], sensor selection [35.27], reliability [35.28–30], and embedded testing [35.31] are now receiving more attention from system developers.

Each sensor type has different characteristics and functional descriptions. Consequently, some approaches aim to develop general methods of modeling sensor systems in a manner that is independent of the physical sensors used. In turn, this enables the performance and robustness of multisensor systems to be studied in a general way. There have been many attempts to provide *the* general model, along with its mathematical basis and description. Some of these modeling techniques concern error analysis and fault tolerance of multisensor systems [35.32–37]. Other techniques are model based, and require a priori knowledge of the sensed object and its environment [35.38–40]. These help fit data to a model, but do not always provide the means to compare alternatives. Task-directed sensing is another approach to devising sensing strategies [35.41–43]. General sensor modeling work has had a considerable influence on the evolution of multisensor fusion architectures.

Another approach to modeling sensor systems is to define sensori-computational systems associated with each sensor to allow design, comparison, transformation, and reduction of any sensory system [35.44]. In this approach, the concept of an information invariant is used to define a measure of information complexity. This provides a computational theory allowing analysis, comparison, and reduction of sensor systems.

In general terms, multisensor fusion architectures may be classified according to the choice along four independent design dimensions:

1. Centralized–decentralized,
2. Local–global interaction of components,
3. Modular–monolithic, and
4. Heterarchical–hierarchical.

The most prevalent combinations are:

- Centralized, global interaction, and hierarchical,
- Decentralized, global interaction, and heterarchical,
- Decentralized, local interaction, and hierarchical,
- Decentralized, local interaction, and heterarchical.

In some cases explicit modularity is also desirable. Most existing multisensor architectures fit reasonably well into one of these categories. These categories make no general commitment to the algorithmic architecture.

If the algorithmic architecture is the predominant feature of a system, it will be characterized as part of multisensor fusion theory in Sect. 35.1; otherwise, it merely differentiates methods within one of the four meta-architectures.

35.2.2 Centralized, Local Interaction, and Hierarchical

Centralized, local interaction and hierarchical architectures encompass a number of system philosophies. Least representationally demanding is the *subsumption architecture* initially proposed by *Braitenberg* [35.45] and popularized by *Brooks* [35.46]. The subsumption multisensor architecture defines behaviors as the basic components, and employs a layered set of behaviors to embody one program (monolithic). Any behavior may utilize the output of other behaviors, and may also inhibit other behaviors. The hierarchy is defined by the layers, although this is not always clear-cut. The major design philosophy is to develop behaviors directly from perception–action loops without recourse to brittle, environment representations. This leads to robustness in operation, but a lack of composite behavior predictability.

A more sophisticated (representationally) behavior-based system is the *distributed field robot architecture* (DFRA) [35.47]. This is a generalization of the sensor fusion effects (SFX) architecture [35.48]. This approach exploits modularity, and aims to achieve both behavior-based and deliberative action, reconfigurability and interoperability through the use of Java, Jini, and XML, fault tolerance, adaptability, longevity, consistent interfaces, and dynamic components. The algorithmic architecture is based on fuzzy logic controllers. Experiments have been demonstrated on outdoor mobile robot navigation.

Other similar architectures of this type include perception action networks *Lee* and *Ro* [35.49, 50], while *Draper* et al. [35.51] focuses on types of information needed to perform tasks (higher-level integration); see also [35.52].

Another approach to this type of sensor fusion is to use artificial neural networks. The advantage is that the user, at least in principle, does not need to understand how sensor modalities relate, nor model the uncertainties, nor in fact determine the structure of the system more than to specify the number of layers in the network and the number of nodes per layer. The neural network is presented with a set of training examples, and must determine through the weights on the neuron connections the optimal mapping from inputs to desired outputs (classifications, control signals, etc.) [35.53, 54].

Various other methods exist; for example, *Hager* and *Mintz* [35.42, 43] defines a task-oriented approach to sensor fusion based on Bayesian decision theory and develops an object-oriented programming framework. *Joshi* and *Sanderson* [35.55] describe a

methodology for addressing model selection and multisensor fusion issues using representation size (description length) to choose (1) model class and number of parameters, (2) model parameter resolution (3) subset of observed features to model, and (4) correspondence to map features to models.

Their approach is broader than an architecture and uses a minimization criterion to synthesize a multisensor fusion system to solve specific two-dimensional (2-D) and three-dimensional (3-D) object recognition problems.

35.2.3 Decentralized, Global Interaction, and Heterarchical

The major example of the decentralized, global interaction meta-architecture is the blackboard system. There have been many examples of blackboard systems developed for data fusion applications. For example, the SEPIA system of *Berge-Cherfaoui* and *Vachon* [35.56] uses logical sensors (see below) in the form of modular agents that post results to a blackboard. The overall architectural goals for blackboards include efficient collaboration and dynamic configuration. Experiments are reported on an indoor robot moving from room to room.

The *MESSIE* (multi expert system for scene interpretation and evaluation) system [35.57] is a scene interpretation system based on multisensor fusion; it has been applied to the interpretation of remotely sensed images. A typology of the multisensor fusion concepts is presented, and the consequences of modeling problems for objects, scene, and strategy are derived. The proposed multispecialist architecture generalized the ideas of their previous work by taking into account the knowledge of sensors, the multiple viewing notion (shot), and the uncertainty and imprecision of models and data modeled with possibility theory. In particular, generic models of objects are represented by concepts independent of sensors (geometry, materials, and spatial context). Three kinds of specialists are present in the architecture: generic specialists (scene and conflict), semantic object specialists, and low-level specialists. A blackboard structure with a centralized control is used. The interpreted scene is implemented as a matrix of pointers enabling conflicts to be detected very easily. Under the control of the scene specialist, the conflict

specialist resolves conflicts using the spatial context knowledge of objects. Finally, an interpretation system with SAR (synthetic aperture radar)/SPOT sensors is described, and an example of a session concerned with bridge, urban area, and road detection is shown.

35.2.4 Decentralized, Local Interaction, and Hierarchical

One of the earliest proposals for this type of architecture is the real-time control system (RCS) [35.58]. RCS is presented as a cognitive architecture for intelligent control, but essentially uses multisensor fusion to achieve complex control. RCS focuses on task decomposition as the fundamental organizing principle. It defines a set of nodes, each comprised of a sensor processor, a world model, and a behavior generation component. Nodes communicate with other nodes, generally in a hierarchical manner, although across-layer connections are allowed. The system supports a wide variety of algorithmic architectures, from reactive behavior to semantic networks. Moreover, it maintains signals, images, and maps, and allows tight coupling between iconic and symbolic representations. The architecture does not generally allow dynamic reconfiguration, but maintains the static module connectivity structure of the specification. RCS has been demonstrated in unmanned ground vehicles [35.59]. Other object-oriented approaches have been reported [35.34, 60].

An early architectural approach which advocated strong programming semantics for multisensor systems is the logical sensor system (LSS). This approach exploits functional (or applicative) language theory to achieve that.

The most developed version of LSS is instrumented LSS (ILSS) [35.22]. The ILSS approach is based on the LSS introduced by *Shilcrat* and *Henderson* [35.61]. The LSS methodology is designed to specify any sensor in a way that hides its physical nature. The main goal behind LSS was to develop a coherent and efficient presentation of the information provided by many sensors of different types. This representation provides a means for recovery from sensor failure, and also facilitates reconfiguration of the sensor system when adding or replacing sensors [35.62].

ILSS is defined as an extension to LSS, and is comprised of the following components (Fig. 35.4):

1. *ILS name*: uniquely identifies a module
2. *Characteristic output vector (COV)*: strongly typed output structure, with one output vector and zero or more input vectors
3. *Commands*: input commands to the module, and output commands to the other modules

4. *Select function*: a selector that detects the failure of an alternate and switches to another alternate if possible
5. *Alternate subnets*: alternative ways of producing the COV_{out} ; it is these implementations of one or more algorithms that carry the main functions of the module
6. *Control command interpreter (CCI)*: interpreter of the commands to the module
7. *Embedded tests*: self-testing routines that increase robustness and facilitate debugging
8. *Monitors*: modules that check the validity of the resulting COVs
9. *Taps*: hooks on the output lines to view different COV values.

These components identify the system behavior and provide mechanisms for online monitoring and debugging. In addition, they provide handles for measuring the runtime performance of the system. Monitors are validity check stations that filter the output and alert the user to any undesired results. Each monitor is equipped with a set of rules (or constraints) that governs the behavior of the COV under different conditions.

Embedded testing is used for online checking and debugging purposes. *Weller* et al. proposed a sensor-processing model with the ability to detect measurement errors and to recover from these errors [35.31]. This method is based on providing each system module with verification tests to verify certain characteristics in the measured data, and to verify the internal and output data resulting from the sensor-module algorithm. The recovery strategy is based on rules that are local to the

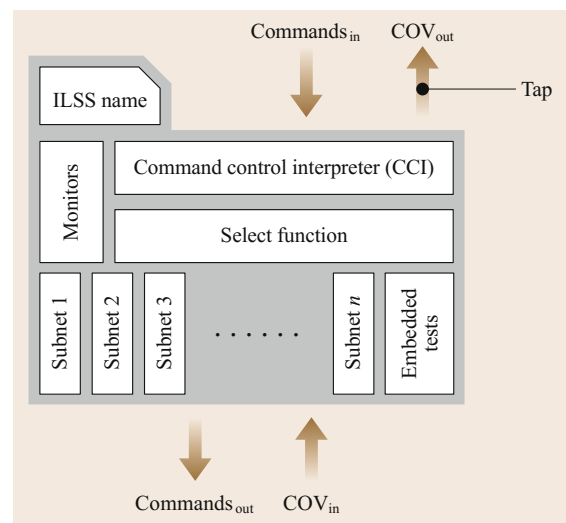

Fig. 35.4 Instrumented logical sensor module

Table 35.1 Canonical components and the roles they play. Multiple ✓ in the same row indicate that some interrole relationships are internalized within a component. *Frame* does not participate in information fusion or decision making but is required for localization and other platform-specific tasks (after [35.21])

Frame								

different sensor modules. ILSS uses a similar approach called *local embedded testing*, in which each module is equipped with a set of tests based on the semantic definition of that module. These tests generate input data to check different aspects of the module, then examine the output of the module using a set of constraints and rules defined by the semantics. These tests can also take input from other modules to check the operation of a group of modules. Examples are given of a wall-posed estimation system comprised of a Labmate platform with a camera and sonars. Many extensions have been proposed for LSS [35.63, 64].

35.2.5 Decentralized, Local Interaction, and Heterarchical

The best example of this meta-architecture is the active sensor network (ASN) framework for distributed data fusion developed by Makarenko et al. [35.21, 65]. The distinguishing features of the various architectures are now described.

Meta-architecture
The distinguishing features of ASN are its commitment to decentralization, modularity, and strictly local interactions (this may be physical or by type). Thus, these are communicating processes. Decentralized means that no component is central to operation of the system, and the communication is peer to peer. Also, there are no central facilities or services (e.g., for communication, name and service lookup or timing). These features lead to a system that is scalable, fault tolerant, and reconfigurable.
Local interactions mean that the number of communication links does not change with the network size. Moreover, the number of messages should also remain constant. This makes the system scalable as well as reconfigurable.

Modularity leads to interoperability derived from interface protocols, reconfigurability, and fault tolerance: failure may be confined to individual modules.

Algorithmic Architecture

There are three main algorithmic components: belief fusion, utility fusion, and policy selection. Belief fusion is achieved by communicating all beliefs to neighboring platforms. A belief is defined as a probability distribution of the world state space.
Utility fusion is handled by separating the individual platform’s partial utility into the team utility of belief quality and local utilities of action and communication. The downside is that the potential coupling between individual actions and messages is ignored because the utilities of action and communication remain local.

The communication and action policies are chosen by maximizing expected values. The selected approach is to achieve point maximization for one particular state and follows the work of Durrant-Whyte et al. [35.11, 66].

Conceptual Architecture

The data types of the system include:
1. *Beliefs*: Current world beliefs
2. *Plans*: Future planned world beliefs
3. *Actions*: Future planned actions.

The definition of component roles leads to a natural partition of the system.
The information fusion task is achieved through the definition of four component roles for each data type: *source*, *sink*, *fuser*, and *distributor*. (Note that the data type action does not have fuser or distributor component roles.)

Connections between distributors form the backbone of the ASN framework, and the information exchanged is in the form of their local beliefs. Similar considerations are used to determine component roles for the decision-making and system configuration tasks.

Logical Architecture

A detailed architecture specification is determined from the conceptual architecture. It is comprised of

six canonical component types as described in Table 35.1 [35.21].

Makarenko then describes how to combine the components and interfaces to realize the use cases of the problem domain in ASN.

Execution Architecture

The execution architecture traces the mapping of logical components to runtime elements such as processes and shared libraries. The deployment view shows the mapping of physical components onto the nodes

of the physical system. The source code view explains how the software implementing the system is organized. At the architectural level, three items are addressed: execution, deployment, and source code organization.

The experimental implementation of the ASN framework has proven to be flexible enough to accommodate a variety of system topologies, platform, and sensor hardware, and environment representations. Several examples are given with a variety of sensors, processors, and hardware platforms.

35.3 Applications

Multisensor fusion systems have been applied to a wide variety of problems in robotics (see the references for this chapter and VIDEO 132, VIDEO 638 and VIDEO 639), but the two most general areas are *dynamic system control* and *environment modeling*. Although there is some overlap between these, they may generally be characterized as:

- *Dynamic system control*: The problem is to use appropriate models and sensors to control the state of a dynamic system (e.g., industrial robot, mobile robot, autonomous vehicle, surgical robot). Usually such systems involve real-time feedback control loops for steering, acceleration, and behavior selection. In addition to state estimation, uncertainty models are required. Sensors may include force/torque sensors, gyros, global positioning system (GPS), position encoders, cameras, range finders, etc..
- *Environment modeling*: The problem is to use appropriate sensors to construct a model of some aspect of the physical environment. This may be a particular object, e.g., a cup, a physical part, a face, or a larger part of the surroundings, e.g., the interior of a building, part of a city or an extended remote or underground area. Typical sensors include cameras, radar, 3-D range finders, infrared (IR), tactile sensors and touch probes (CMMs), etc. The result is usually expressed as geometry (points, lines, surfaces), features (holes, sinks, corners, etc.), or physical properties. Part of the problem includes the determination of optimal sensor placement.

35.3.1 Dynamic System Control

The EMS-Vision system [35.67] is an outstanding exemplar of this application domain. The goal is to

develop a robust and reliable perceptual system for autonomous vehicles. The development goals, as stated by the EMS-Vision team, are:

- COTS components
- Wide variety of objects modeled and incorporated into behaviors
- Inertial sensors for ego-state estimation
- Peripheral/foveal/saccadic vision
- Knowledge and goal driven behavior
- State tracking for objects
- 25 Hz real-time update rate.

The approach has been in development since the 1980s. Figure 35.5 shows the first vehicle to drive fully autonomously on the German autobahn for 20 km and at speeds up to 96 km/h.

Information from inertial and vision sensors is combined to produce a road scene tree (Fig. 35.6). A four-

Fig.35.10a-i A synopsis of the ANSER II autonomous network and its operation. **(a-c)** Main system components: **(a)** air vehicle, **(b)** ground vehicle, **(c)** human operative. **(d-e)** The perception process: **(d)** top three dimensions of features discovered from ground-based visual sensor data along with the derived mixture model describing these feature properties, **(e)** sector of the overall picture obtained from fusing air vehicle (UAV), ground vehicle (GV), and human operator (HO) information. Each set of ellipses corresponds to a particular feature and the labels represent the identity state with highest probability. **(f-i)** Sequential fusion process for two close landmarks: **(f)** a tree and a red car, **(g)** bearing-only visual observations of these landmarks are successively fused, **(h)** to determine location and identity **(i)**. Note the Gaussian mixture model for the bearing measurement likelihood

dimensional (4-D) generic object representation is built which includes background knowledge of the object (e.g., roads), its behavioral capabilities, object state and variances, and shape and aspect parameters. Figure 35.7 shows the 4-D inertial/vision multisensor guidance system, while Fig. 35.8 shows the hardware aspects.

In summary, the EMS-Vision system is an interesting and powerful demonstration of multisensor fusion for dynamic system control.

35.3.2 ANSER II: Decentralized Data Fusion

Decentralized data fusion (DDF) methods were initially motivated by the insight that the *information* or canonical form of the conventional Kalman filter data fusion algorithm could be implemented by simply adding information contributions from observations as shown in (35.41). As these (vector and matrix) additions are commutative, the update or data fusion process can

be optimally distributed amongst a network of sensors [35.11, 12, 68]. The aim of the ANSER II project was to generalize the DDF method to deal with non-Gaussian probabilities for observations and states, and to incorporate information from a diversity of sources including uninhabited air and ground vehicles, terrain databases, and human operatives.

The mathematical structure of a DDF sensor node is shown in Fig. 35.9. The sensor is modeled directly in the form of a likelihood function. Once instantiated with an observation, the likelihood function is input to a local fusion loop which implements a local form of the Bayesian time and observation update of (35.7) and (35.8). Network nodes accumulate probabilistic information from observation or communication and exchange mutual information (information gain) with other nodes in the network [35.21]. This mutual information is transmitted to and assimilated by other nodes in the network in an ad hoc manner. The result is that all nodes in the network obtain a single integrated posterior-probability-based all-node observations.

The ANSER II system consists of a pair of autonomous air vehicles equipped with infrared and visual sensors, a pair of unmanned ground vehicles equipped with visual and radar sensors, and additional information provided by geometric and hyperspectral databases, along with information input by human operatives [35.69]. The likelihood functions for single-

sensor features are obtained through a semisupervised machine learning method [35.70]. The resulting probabilities are modeled in the form of a mixture of Gaussians. Each platform then maintains a bank of decentralized, non-Gaussian Bayesian filters for the observed features, and transmits this information to all other platforms. The net result is that each platform maintains a complete map of all features observed by all nodes in the network. Multiple observations of the same feature, possibly by different platforms, result in an increasingly accurate estimate of the feature location for all nodes. A corresponding discrete probability measure is used for Fig. 35.10 shows a synopsis of the operation of the ANSER II system.

The ANSER II system demonstrates a number of general principles in Bayesian data fusion methods, specifically the need to model sensors appropriately through the likelihood function, and the possibility of building very different data fusion architectures from the essential Bayesian form.

35.3.3 Recent Developments

There have been recent developments in multisensor fusion methods: see [35.71–73] for more theoretical work, vision and biomedical applications [35.74–77], tracking and terrain classification [35.78–81], and robotics and automation [35.82–87].

35.4 Conclusions

Multisensor data fusion has progressed greatly in the last few decades; further advances in the field will be documented in the robotics and multisensor fusion and integration conference and journal literature. Robust applications are being fielded based on the body of theory and experimental knowledge produced by the research community. Current directions of interest include:

1. Large-scale, ubiquitous sensor systems,
2. Bio-based or biomimetic systems,
3. Medical in situ applications,
4. Wireless sensor networks.

Representative large-scale examples include intelligent vehicle and road systems, as well as instrumented contexts such as cities. Biological principles may provide fundamentally distinct approaches to the exploitation of dense, redundant, correlated, noisy sensors, especially when considered as part of a Gibbsian framework for behavioral response to environmental stimuli.

Another issue here is the development of a theoretical understanding of sensor system development, adaptivity, and learning with respect to the particular context in which the system is deployed.

Further pushing the envelope of both technology and theory will permit the introduction of micro- and nanosensors into the human body and allow the monitoring and locally adaptive treatment of various illnesses. Finally, a more-complete theoretical framework that encompasses system models for wireless sensor networks is still required. This should include models of the physical phenomena being monitored, as well as operational and network issues. Finally, numerical analysis of the algorithmic properties of data-driven systems with sensor data error sources must be unified with the analysis of truncation, roundoff, and other errors.

A firm foundation exists upon which to build these new theories, systems, and applications. It will be a vibrant area of research for years to come.

Part D, Manipulation and Interfaces, is separated into two subparts; the first half is concerned with manipulation where frameworks of modeling, motion planning, and control of grasp and manipulation of an object are addressed, and the second half is concerned with interfaces where physical human–robot interactions are handled. Humans can achieve grasping and manipulation of an object dexterously through hand–arm coordination. An optimum control skill for such a redundant system is naturally and gradually acquired through experience in our daily life. Especially, fingers play an important role for expressing human dexterity. Without dexterous fingers, it is hard for us to handle any daily tool, such as a pencil, keyboard, cup, knife, or fork. This dexterity is supported with active and passive compliance as well as the multiple sensory organs existing at the fingertip. Such dexterous manipulation enables us to clearly differentiate humans from other animals. Thus, manipulation is one of the most important functions for humans. We eventually acquired the current shape of finger, the sensory organs, and skill for manipulation, through a long history of evolution, over more than six million years. While humans and robots are largely different in terms of actuators, sensors, and mechanisms, achieving dexterous manipulation like that of a human in a robot is a challenging subject in robotics. As we overview current robot technology, however, we observe that the dexterity of robots is still far behind that of humans. With this overview, we now provide a brief synopsis of each chapter in the first half of Part D.

Chapter 36, Motion for Manipulation Tasks, discusses algorithms that generate motion for manipulation tasks at the arm level, especially in an environment, by using the configuration space formalism. While in previous chapters (6 and 7) the focus was on specific algorithmic techniques for robot motion, this chapter is focused on a specific application for robot manipulation. The important example of assembly motion is discussed through the analysis of contact states and compliant motion control.

Chapter 37, Contact Modeling and Manipulation, provides the contact modeling on rigid contact with and without friction, and also the modeling on soft contact, such as elastic and viscoelastic contact interfaces. Kinematics and mechanics with friction are precisely handled under rigid-body contact. The selection matrix \mathbf{H} is introduced to understand the force and velocity constraints at the contact interface. Pushing manipulation is also addressed by using the concept of the friction limit surface.

Chapter 38, Grasping, discusses based on the closure property, grasping with many examples, supposing multifingered robotic hands. A strong constraint for grasping is the unilateral characteristic, where a fingertip can push but not pull an object through a contact point. The rigid-body model is further extended for considering compliance in grasping with robotic hands having a low number of degrees of freedom (DOFs). Kinematics and closure issues are also addressed under this unilateral constraint.

Chapter 39, Cooperative Manipulators, addresses the strategies for controlling both the motion of cooperative system and the interaction forces between the manipulators and the grasped object when two manipulator arms firmly grasp a common object. It should be noted that this chapter allows the bilateral constraint where both directional force and moment are permissible. A general cooperative task-space formulation is introduced for different classes of multiarm robotic systems.

Chapter 40, Mobile Manipulation, focuses on research conducted on an experimental platform that combines capabilities in mobility and manipulation. Furthermore, it involves the interaction between the robots and real-world environment, unstructured environments. The main research objective here is to maximize task generality of autonomous robotic systems, under minimizing the dependence on task-specific, hard-coded, or narrowly-relevant information.

Chapter 41, Active Manipulation for Perception, covers perceptual methods in which manipulation is an integral part of perception. There are advantages to use manipulation rather than vision for perception. For example, manipulation can be used to sense in poor-visibility conditions, and also to determine properties that require physical interaction. This chapter includes the methods that have been developed for inference, planning, recognition, and modeling in sensing-via-manipulation approaches are cover.

Without dexterity like that of humans, future robots will not be able to work instead of humans in environments where human cannot enter. In this sense, the implementation of dexterity into robots is one of the highlights of future robot design. Chapters 36–41 provide a good hint for enhancing dexterity for robots.

The second half of Part D addresses interfaces where humans control a robot or multiple robots through direct or indirect contact with robot(s). We now

provide a brief synopsis of each chapter in the second half of Part D.

Chapter 42, Haptics, discusses robotics devices that allow human operators to experience the sense of touch in remote or virtual environment. Two classes of force feedback haptic devices are discussed. One is an admittance device that senses the force applied by the operator and constrains the operator's position to match the appropriate deflection of a simulated object or surface; the other is an impedance haptic device that senses the position of the operator and then applies a force vector to the operator according to the computed behavior of the simulated object or surface. Haptic rendering from real time three-dimensional (3-D) image is also introduced in this chapter.

Chapter 43, Telerobotics, starts with a discussion on the classification of three different concepts: direct control where all slave motions are directly controlled by the user via the master interface, shared control where task execution is shared between direct control and local sensory control, and supervisory control

where the user and slave are connected loosely with strong local autonomy. Various control issues such as lossy communication with Internet and operation with mobile robots, are also addressed.

Chapter 44, Networked Robots, focuses on the framework of computer networks which offer extensive computing, memory, and other resources that can dramatically improve performance. The chapter covers a wide span from the history of networked robots as it evolves from teleoperation to cloud robotics to how to build a networked robot. The very recent progress on cloud robotics and potential topics for future research are included later in the chapter.

In Haptics (Chap. 42) direct contact between human and robot is made, while in both Telerobotics (Chap. 43) and Networked Robots (Chap. 44), an appropriate distance between the human and robot is kept. One of the main issues is how to maintain appropriate control performance of the system in the presence of humans or a time lag between humans and robots.

36. Motion for Manipulation Tasks

James Kuffner, Jing Xiao

This chapter serves as an introduction to Part D by giving an overview of motion generation and control strategies in the context of robotic manipulation tasks. Automatic control ranging from the abstract, high-level task specification down to fine-grained feedback at the task interface are considered. Some of the important issues include modeling of the interfaces between the robot and the environment at the different time scales of motion and incorporating sensing and feedback. Manipulation planning is introduced as an extension to the basic motion planning problem, which can be modeled as a hybrid system of continuous configuration spaces arising from the act of grasping and moving parts in the environment. The important example of assembly motion is discussed through the analysis of contact states and compliant motion control. Finally, methods aimed at integrating global planning with state feedback control are summarized.

36.1 Overview

Part D of this handbook is concerned with the interfaces that connect robots to their environment. We differentiate three such interfaces, depicted in Fig. 36.1. The first interface, between the robot and the computer, is primarily concerned with the automatic generation of motion for performing a task. The second interface is concerned with the physical interaction between the robot and the environment. This chapter relates both interfaces in the context of manipulation tasks. It is focused on automatic specification, planning, and execution of motion of the robot manipulator or the manipulated object to meet a task goal under the constraints of the physical environment. Chapters 37–39, 40, and 42 address other important issues pertaining to the second interface, such as the physical characteristics of contacts between the robot and the environment, grasping and active manipulation (i.e., the interaction between the robot and the object for manipulation), the interaction between cooperative manipulators, and the interaction between mobility and manipulation. The third interface, described in Chaps. 41, 43, and 44, lies between humans and robots. Key issues that need to be addressed involve displaying appropriate sensor information to humans, or permitting humans to interactively specify the task or motion a robot is supposed to perform.

Manipulation refers to the process of moving or rearranging objects in the environment [36.1]. To perform a *manipulation task*, a robot establishes physical contact with objects in the environment and subsequently moves these objects by exerting forces and moments. The object to be manipulated can be large or small, and may serve various purposes in relation to the manipulation task (e.g., flipping a switch, opening a door, polishing a surface). In the context of automated assembly and industrial manipulation, the object to be manipulated is often referred to as a *part*. The *end-effector* generally refers to the link of the *manipulator* that makes contact and applies forces to the *part*. The *end-effector* is so named as it is often the end link in a se-

rial kinematic chain. However, complex manipulation tasks may require the simultaneous exertion of multiple forces and moments at different contact points as well as the execution of sequences of force applications to several objects.

To understand the challenge of generating the motion required for the execution of a manipulation task, we will consider the classic example of inserting a peg into a hole. The mobile manipulator shown in Fig. 36.2 is commanded to perform the peg insertion *manipulation task*, whose general problem structure arises in a number of contexts such as compliant assembly. For simplicity, we will only consider the *transfer motion* (Sect. 36.3) and assume that the robot has already established a stable grasp (Chap. 38) and is holding the peg. If the clearance between the peg and the hole is very small, the peg may not be able to enter the hole easily, and often some contact occurs. In order to guide the peg successfully into the hole, the robot has to deal with the possible contact states between the peg and the hole (Sect. 36.4) and select an appropriate sequence of control strategies that will result in successful completion of the task.

The peg-and-hole example illustrates that successful robotic manipulation involves dealing with models of object geometry and contact in the presence of uncertainty. There are various kinds of uncertainty, including modeling, actuation, and sensing uncertainty. To plan motion strategies in the presence of uncertainty poses difficult computational challenges. Historically, motion planning for manipulation has been divided into *gross motion planning* and *fine motion planning*. The former involves reasoning about the manipulator motion on the macro scale and considers its overall global movement

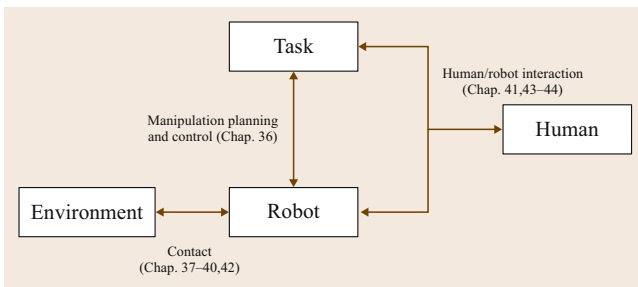

Fig. 36.1 Overview of Part D

Fig. 36.2 A mobile manipulator inserting a peg into a hole

strategy, while the latter considers how to deal with uncertainty to accomplish a task requiring high precision robustly. The primary reason for the historical division stems from attempts to simplify the various aspects of the problem into something computationally tractable. Assuming that the uncertainty in actuator position, object models, and environment obstacle shapes can be bounded, gross motion planning can be formulated primarily in terms of geometry (Sect. 36.3). As the robot or the manipulated object makes contact with the environment, such as in the example of the insertion task, fine motion planning techniques are employed to take into account contact geometry, forces, friction, and uncertainty effectively (see Mason's book [36.1] and [36.2, 3] for an overview and historical perspective on fine motion strategies for manipulation tasks).

This peg-and-hole insertion example also illustrates that motion in the context of manipulation tasks is subject to *constraints*. These constraints have to be maintained to perform the task successfully. The specific constraints depend on the type of manipulation task, but they may include contact constraints, position, and force constraints for the point at which the manipulator makes contact with the environment, kinematic and dynamic constraints imposed by the mechanism and its actuation capabilities, posture constraints that specify behavior to be performed in addition to the manipulation task, reactive obstacle avoidance in an unpredictably changing environment, and global motion constraints to ensure that a specific goal location is attained. These motion constraints are imposed by the task, by the kinematics of the mechanism performing the task, by the actuation capabilities of the mechanism, and by the environment.

To ensure that constraints are satisfied in spite of uncertainty, sensory information (see Part C – Sensing and Perception) is considered in the context of feedback control loops (Chaps. 8 and 47). Depending on the type of constraint, this feedback has to be considered at various time scales. For example, the exertion of a constant force on an object in the environment requires high-frequency feedback at rates up to 1000 Hz. At the other end of the time scale, we consider changes to the global connectivity of the environment. These changes, resulting from opening doors or moving obstacles, for example, occur relatively slowly or infrequently and feedback about these changes only has to be considered a few times per second. Figure 36.3 graphically illustrates a task-dependent ordering of motion constraints encountered in manipulation tasks and their associated feedback requirements.

This chapter is concerned with algorithms that generate motion for manipulation tasks. Previous chapters already discussed planning algorithms (Chap. 7 and

control methods (Chap. 8). While in these two former chapters the focus was on specific algorithmic techniques for robot motion, the current chapter is focused on a specific application, namely robotic manipulation. This application dictates motion constraints and their feedback requirements that will have to be satisfied during the motion for a manipulation task. In contrast, the methods discussed in the two aforementioned chapters each only address a subset of the motion constraints, as indicated in Fig. 36.3.

This chapter first discusses task-level control in Sect. 36.2. Task-level control describes a set of techniques to control a robotic mechanism in terms of its contact points with the environment. These contact points are controlled to perform motion that accomplishes a specific manipulation task. This means that, instead of directly controlling the mechanism, task-relevant points on the mechanism, so-called *operational points*, are controlled. This indirect control provides an intuitive means to specify desired motion for manipulation tasks.

Section 36.3 gives an overview of the configuration space formalization for manipulation planning, and how it can be cast as a classical motion planning problem (Chap. 7). Through this formalism, we can gain an understanding and intuition regarding how the geometry and relative positions of the manipulator, the manipulated objects, and the obstacles in the workspace determine both the geometry and topological structure of the manipulation configuration space. As we shall see, there are often an infinite number of possible ways to accomplish a manipulation task. Thus, the challenge in manipulation planning is to develop methods that deal effectively with the combinatorics of the search over all possible motions.

Section 36.4 addresses planning motion for assembly tasks, for which the peg-in-hole insertion is a typical example. The focus is on motion constrained by contact, called *compliant motion*. There are two broad

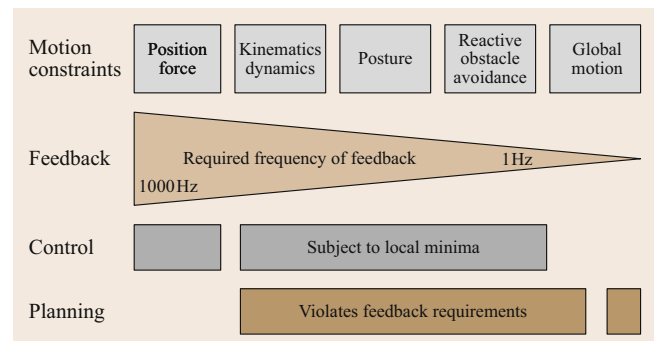

Fig. 36.3 Examples of motion constraints encountered in manipulation tasks and their feedback requirements

classes of assembly strategies involving compliant motion; one class is through special mechanism or control, called *passive compliance*, and the other is through active reasoning of contact states, called *active compliant motion*. Fine motion planning is discussed within the class of active compliant motion.

Methods from task-level control and manipulation planning address aspects of motion in a complementary fashion. While control methods are able to satisfy the feedback requirements of manipulation tasks, they often do not account for the overall global progress

in accomplishing the manipulation task. Manipulation planners, on the other hand, reason about the global nature of the task at the high level, but are often computationally too expensive to deal with uncertainty or satisfy the high-frequency feedback requirements of manipulation tasks. A robust and skillful manipulator must satisfy all feedback requirements while at the same time ensuring the accomplishment of the manipulation task. Section 36.5 discusses various techniques that offer a unified view of planning and control for manipulation tasks.

36.2 Task-Level Control

To perform a manipulation task, a robot has to establish contact with the environment. Through contact points the robot is able to apply forces and moments to objects. By controlling the position and velocity of the contact points as well as the forces acting at them, the robot causes the desired motion of objects, thereby performing the manipulation task. The programming of such a task is most conveniently accomplished by directly specifying positions, velocities, and forces at the contact points, rather than by specifying the joint positions and velocities required to achieve them.

Consider the manipulation task of serving a cup of water shown in Fig. 36.2. This task can easily be specified by providing a trajectory for the cup's motion. To determine a joint space trajectory that achieves the same motion, however, would be much more complex. One would have to rely on inverse kinematics (Sect. 2.9), which can be computationally challenging. More importantly, the task constraints imposed on the cup's motion do not uniquely specify the cup's trajectory. For example, while the cup is not allowed to tilt, it can be delivered to the goal location in any vertical orientation. Such task constraints can easily be specified in terms of the object motion – at the task level – but would be very difficult to characterize in terms of joint trajectories. Operational space control is therefore a natural choice for performing manipulation tasks. We will see in Sect. 36.2.3 that the operational space framework provides important additional advantages over joint space control in the context of redundant manipulators.

The advantages associated with task-level control come at the cost of depending on the manipulator Jacobian. For singular configurations of the manipulator (Chap. 4), the manipulator Jacobian is not well defined. In these configurations, task-level control of a manipulator becomes unstable. Special care has to be applied to prevent the manipulator from entering these con-

figurations, or to resort to specialized controllers in the proximity of these configurations. Most commonly, the manipulator is controlled so as to avoid singular configurations.

36.2.1 Operational Space Control

Task-level control – also called operational space control [36.4,5] (Sect. 8.2) – specifies the behavior of a robot in terms of operational points rather than joint positions and velocities. An operational point is an arbitrary point on the robot that is required to perform a particular motion or to exert a specified force to accomplish a manipulation task. In a serial-chain manipulator arm the operational point is most commonly chosen to coincide with the end-effector. More complex, branching mechanisms, such as humanoid robots, but also redundant serial-chain mechanisms, can have several operational points. To specify positions, velocities, accelerations, forces, and moments at the operational point, it is convenient to define a coordinate system with an origin that coincides with the operation point. This coordinate frame is called the operational frame. The orientation of the frame should be chosen in accordance with the task. For now we will ignore the orientation, however, and only consider tasks that require positioning of the operational point. In Sect. 36.2.2, we will consider more general tasks, combining position and force control.

Let us consider an operational point \mathbf{x} on a robot. The relationship between the joint velocities $\dot{\mathbf{q}}$ and the velocity of the operational point $\dot{\mathbf{x}}$ is given by the Jacobian matrix of the mechanism (Sect. 2.8) at the operational point \mathbf{x}

$$\dot{\mathbf{x}} = \mathbf{J}_x(\mathbf{q})\dot{\mathbf{q}}. \quad (36.1)$$

Note that the Jacobian \mathbf{J} depends on the placement of the operational point \mathbf{x} , and on the current configura-

tion \mathbf{q} of the robot. For simplicity, we will omit this dependency from our notation and just write $\dot{\mathbf{x}} = \mathbf{J}\dot{\mathbf{q}}$. From (36.1) we can derive an expression for the instantaneous torques $\boldsymbol{\tau}$ acting at the joints when the forces and moments described by \mathbf{F} is applied at the operational point \mathbf{x}

$$\boldsymbol{\tau} = \mathbf{J}^T(\mathbf{q})\mathbf{F}_x. \quad (36.2)$$

The vector \mathbf{F} captures the task to be performed at operational point \mathbf{x} . If the task specifies the complete position and orientation of the operational frame, \mathbf{F} will be given by $\mathbf{F} = (f_x, f_y, f_z, u_x, u_y, u_z)$, where f and u designate forces along and moments about the respective axes. (For easy of presentation, we will refer to \mathbf{F} as a force vector, even if it describes forces and moments. The execution of such a task requires a manipulator with at least six degrees of freedom. If a task does not specify one of the components of \mathbf{F} , this component can be omitted and the corresponding column of the Jacobian matrix is dropped (or a manipulator with fewer than six degrees of freedom can be used to accomplish the task). For example, dropping u_z would indicate that the orientation about the z -axis is not specified by the task. The motion behavior in the dimensions of the task space that have been dropped is unspecified and the robot will float in these dimensions [36.4]. In Sect. 36.2.3 we will discuss how additional behavior can be performed in these unspecified dimensions of the task space.

Similarly to joint space control, we have to account for manipulator dynamics to achieve acceptable performance in operational space control. Using (36.1), we can project the joint space dynamics into operational space to obtain

$$\mathbf{F}_x = \boldsymbol{\Lambda}(\mathbf{q})\ddot{\mathbf{x}} + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}), \quad (36.3)$$

where $\boldsymbol{\Lambda}$ is the operational space inertial matrix, $\boldsymbol{\Gamma}$ captures centrifugal and Coriolis forces in operational space, and $\boldsymbol{\eta}$ compensates for gravity forces. This equation pertains to a particular operational point. Intuitively speaking, the operational space inertia matrix $\boldsymbol{\Lambda}$ captures the resistance of the operational point to acceleration along and about different axes. More details about operational space control and its relationship to joint space control are provided in Sect. 8.2 (motion control, joint space versus operational space control).

36.2.2 Combined Force and Position Control

Let us consider the example task of controlling the motion of a peg inside a hole. We assume the peg is already inserted into the hole and rigidly connected to the robot's end-effector. We attach the operational frame to

a point on the peg so that its z -axis is aligned with the desired direction of motion of the peg inside the hole. To perform this task, the robot has to control the position of the peg along the z -axis of the operational frame and it also has to control contact forces between the peg and the hole to avoid jamming. Thus, the task of moving a peg inside a hole requires that position and force control be seamlessly integrated.

To address contact forces within the operational space framework, we rewrite (36.3) as

$$\mathbf{F}_x = \mathbf{F}_c + \boldsymbol{\Lambda}(\mathbf{q})\mathbf{F}_m + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}), \quad (36.4)$$

where \mathbf{F}_c represents the contact forces acting at the end-effector [36.4]. We can replace $\dot{\mathbf{x}}$ with \mathbf{F}_m because $\dot{\mathbf{x}}$ is acting on a dynamically decoupled system, i. e., a system that acts like a unit point mass. We can now control forces and motion in the operational frame by selecting the following control structure

$$\mathbf{F}_x = \mathbf{F}_m + \mathbf{F}_c, \quad (36.5)$$

where

$$\mathbf{F}_m = \boldsymbol{\Lambda}(\mathbf{q})\boldsymbol{\Omega}\mathbf{F}'_m + \boldsymbol{\Gamma}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{x}} + \boldsymbol{\eta}(\mathbf{q}), \quad (36.6)$$

$$\mathbf{F}_c = \boldsymbol{\Lambda}(\mathbf{q})\tilde{\boldsymbol{\Omega}}\mathbf{F}'_c, \quad (36.7)$$

where $\boldsymbol{\Omega}$ and $\tilde{\boldsymbol{\Omega}}$ represent complementary task specification matrices [36.4] that determine along which directions the end-effector is position controlled and along which it is force controlled. By selecting $\boldsymbol{\Omega}$ appropriately, the combination of position and force control can be tailored to the task. In its simplest form, $\boldsymbol{\Omega}$ and $\tilde{\boldsymbol{\Omega}} = \mathbf{I} - \boldsymbol{\Omega}$ are diagonal matrices. The i -th diagonal entry of $\boldsymbol{\Omega}$ is 1 if the i -th operational coordinate of the end-effector is position controlled and 0 if it is force controlled. In this simplest case, positions and forces are controlled along axes of the same coordinate frame. The concept of task specification matrix can be extended to include differently oriented coordinate frames for position and force control [36.4].

Once the force \mathbf{F}_x has been computed as given by (36.5), the corresponding joint torques used to control the robot are computed based on (36.1).

36.2.3 Operational Space Control of Redundant Mechanisms

The full expressiveness of task-level control comes to bear in the context of redundant manipulators. A manipulator is considered redundant with respect to the task it is performing if it has more degrees of freedom than required by the task. For example, the task of holding a cup of water only specifies two degrees of freedom,

namely the two rotations about the axes spanning the horizontal plane – this task has two degrees of freedom. The mobile manipulator shown in Fig. 36.2 has ten degrees of freedom, leaving eight redundant degrees of freedom with respect to the task.

The operational space framework for task-level control of redundant manipulators decomposes the overall motion behavior into two components. The first component is given by the task, specified in terms of forces and moments \mathbf{F}_{task} acting at an operational point. This vector \mathbf{F} is translated into a joint torque based on (36.2): $\boldsymbol{\tau} = \mathbf{J}^T \mathbf{F}_{\text{task}}$. For a redundant manipulator, however, the torque vector $\boldsymbol{\tau}$ is not uniquely specified and we can select from a set of task-consistent torque vectors. The operational space framework performs this selection by considering a secondary task, the so-called posture behavior, making up the second component of the overall motion behavior. Posture behavior can be specified by an arbitrary torque vector $\boldsymbol{\tau}_{\text{posture}}$. To ensure that this additional torque does not affect the task behavior (\mathbf{F}_{task}), the torque $\boldsymbol{\tau}_{\text{posture}}$ is projected into the null space \mathcal{N} [36.6] of the task Jacobian \mathbf{J} . The null space of the Jacobian is the space orthogonal to the one spanned by \mathbf{J} and will be of rank $N_J - k$, where N_J is the number of degrees of freedom of the manipulator and $k = \text{rank}(\mathbf{J})$. The torque $\mathbf{N}^T \boldsymbol{\tau}_{\text{posture}}$ resulting from the null space projection is task consistent, i.e., it is guaranteed not to affect the behavior of the operational point. Since the vector $\mathbf{N}^T \boldsymbol{\tau}_{\text{posture}}$ may not lie entirely within the null space of \mathbf{J} , however, the execution of the posture behavior cannot be guaranteed.

The operational space task ($\mathbf{J}^T \mathbf{F}_{\text{task}}$) and the posture behavior ($\mathbf{N}^T \boldsymbol{\tau}_{\text{posture}}$) are combined to obtain the general expression for the torque-level decomposition of the overall motion behavior

$$\boldsymbol{\tau} = \mathbf{J}^T \mathbf{F}_{\text{task}} + \mathbf{N}^T \boldsymbol{\tau}_{\text{posture}}. \quad (36.8)$$

The null-space projection \mathbf{N} associated with the task Jacobian \mathbf{J} can be obtained by

$$\mathbf{N} = \mathbf{I} - \bar{\mathbf{J}}\mathbf{J}, \quad (36.9)$$

where \mathbf{I} is the identity matrix, and $\bar{\mathbf{J}}$ is the dynamically consistent generalized inverse of \mathbf{J} , given by

$$\bar{\mathbf{J}} = \mathbf{H}^{-1} \mathbf{J}^T \boldsymbol{\Lambda}, \quad (36.10)$$

where \mathbf{H} is the joint space inertia matrix and $\boldsymbol{\Lambda}$ is the operational space inertia matrix for the operational point for which \mathbf{J} is defined. The use of this specific inverse to compute the null-space projection results in the selection of the task-consistent torque vector that minimizes kinetic energy.

36.2.4 Combining Mobility and Manipulation

The operational space framework does not distinguish between degrees of freedom used for mobility and those used for manipulation. The end-effector-centric perspective of this approach considers all degrees of freedom to be in service to position and move the end-effector. An explicit coordination of manipulation and mobility for task-level control is not necessary.

A computationally efficient approach for coordinating manipulation and mobility was introduced in [36.7]. A similar, schema-based coordination of manipulation and mobility in the presence of dynamic obstacles was demonstrated in [36.8]. This approach is based on (36.2) and projects the forces that are derived from various schemas into the configuration space of the robot to determine its motion. Another coordination approach for manipulation and mobility considers a given end-effector path and generates a path of the base that maintains manipulability criteria [36.9]. This underlying representation of mobile manipulators can also be used to generate obstacle avoidance behavior of the base for a given end-effector path [36.10].

The coordination of a nonholonomic mobility platform and a cart-pushing task is addressed in [36.11]. In [36.12], an analysis of the task space for a mobile base with two manipulators is presented. Such a system with two manipulator arms can be viewed as a branching kinematic chain. Section 36.6 discusses extensions to the operational space framework to such branching mechanisms.

36.2.5 Combining Multiple Task Behaviors

The concept of decomposing a redundant robot's overall motion into task and posture behavior can be generalized to an arbitrary number of behaviors [36.13, 14]. Assume a set of n tasks T_i , where T_i has higher priority than T_j if $i < j$. Every task T_i is associated with a force vector \mathbf{F}_i and the corresponding joint torque $\boldsymbol{\tau}_i$. These tasks can be performed simultaneously by projecting the joint torque associated with each task into the combined null space of all tasks with higher priority, just as task and posture behavior were combined in the previous section. The null-space projection ensures that the execution of task i does not affect the execution of tasks with higher priority, given by the set $\text{prec}(i)$.

Given a task i , the joint torque consistent with the set of higher priority tasks $\text{prec}(i)$ can be obtained by projecting $\boldsymbol{\tau}_i$ into the combined null space of $\text{prec}(i)$,

$$\boldsymbol{\tau}_{i|\text{prec}(i)} = \mathbf{N}_{\text{prec}(i)}^T \boldsymbol{\tau}_i, \quad (36.11)$$

where the combined null space $N_{\text{prec}(i)}^T$ is computed as

$$N_{\text{prec}(n)} = N_{n-1}N_{n-2} \cdots N_1. \quad (36.12)$$

We say that $\tau_{i|\text{prec}(i)}$ is the torque for task i given the preceding tasks $\text{prec}(i)$. Applying this torque to the robot will not affect the execution of higher-priority tasks. The original torque vector τ_i can be computed based on (36.2).

Given the ability to compute a task torque that is consistent with preceding tasks we are able to combine an arbitrary number of tasks into a single motion behavior

$$\tau = \tau_1 + \tau_{2|\text{prec}(2)} + \tau_{3|\text{prec}(3)} + \cdots \tau_{n|\text{prec}(n)}, \quad (36.13)$$

where τ is the torque used to control the robot.

Note that τ_1 is not projected into any null space, since it is the task with the highest priority. Task 1 is therefore performed in the full space defined by the robot's kinematics. If the robot has N degrees of freedom, this space has N dimensions. As the number of tasks performed on the robot increases, the null-space projections $N_{\text{prec}(i)}$ will project the N -dimensional torque vectors associated with lower-priority tasks into a subspace of decreasing dimension. Eventually, the null space will be reduced to the trivial case, when all torque vectors are projected onto the null vector. This prevents lower-priority tasks from being executed. The dimensionality of the null space of tasks $\text{prec}(i)$ can be computed by counting the nonzero singular values [36.6] of $N_{\text{prec}(i)}$, permitting a programmatic assessment of task feasibility.

If the execution of a particular task has to be guaranteed, it should be associated with task 1 in (36.13). Therefore, the highest-priority task is generally used for hard constraints that under no circumstances should be violated. These constraints may include contact constraints, joint limits, and balancing in the case of humanoid robots, for example (Chap. 67).

The projection of (36.11) maps the torque τ_i of task i into the null space of all preceding tasks. This projection also scales the vector, which may significantly impair the execution of task i . This effect can be reduced by scaling the desired accelerations \ddot{x} at the operational point with the task-consistent inertia matrix $\Lambda_{i|\text{prec}(i)}$, given by

$$\Lambda_{i|\text{prec}(i)} = \left(\mathbf{J}_{i|\text{prec}(i)} \mathbf{H}^{-1} \mathbf{J}_{i|\text{prec}(i)}^T \right)^{-1}, \quad (36.14)$$

where \mathbf{H} is the joint space inertia matrix and

$$\mathbf{J}_{i|\text{prec}(i)} = \mathbf{J}_i N_{\text{prec}(i)} \quad (36.15)$$

is the task Jacobian consistent with all preceding tasks. This Jacobian projects operational space forces into joint torques that do not cause any acceleration at the operational points of tasks in $\text{prec}(i)$. The task-consistent inertia matrix $\Lambda_{i|\text{prec}(i)}$ then captures the inertia perceived at the operational point when its motion is limited to the subspace consistent with all preceding tasks.

Using the task-consistent inertia matrix, we can obtain the task-consistent operational space dynamics by projecting the joint space dynamics into the space defined by the dynamically consistent inverse of $\mathbf{J}_{i|\text{prec}(i)}$. Inverting (36.2) and replacing τ based on (36.2) we obtain

$$\mathbf{J}_{i|\text{prec}(i)}^T (\mathbf{H}(\mathbf{q}) + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}}) + \tau_g(\mathbf{q})) = \tau_{k|\text{prec}(i)}, \quad (36.16)$$

which yields the task-consistent equivalent to (36.3)

$$\mathbf{F}_{i|\text{prec}(i)} = \Lambda_{i|\text{prec}(i)} \ddot{\mathbf{x}} + \Gamma_{i|\text{prec}(i)} \dot{\mathbf{x}} + \eta_{i|\text{prec}(i)}, \quad (36.17)$$

where $\Lambda_{i|\text{prec}(i)}$ is the task-consistent operational space inertial matrix, $\Gamma_{i|\text{prec}(i)}$ captures centrifugal and Coriolis forces in operational space, and $\eta_{i|\text{prec}(i)}$ compensates for gravity forces. Equation 36.17 can be used to control a task at a particular operational point in a task-consistent manner, i.e., without causing acceleration at the operational points associated with the tasks in $\text{prec}(i)$. Note that in practice the terms $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ and $\tau_g(\mathbf{q})$ can be computed in the joint space; they only need to be accounted for once in the case of multiple tasks.

Referring back to Fig. 36.3, we can analyze the effectiveness of the operational space framework. The control of operational points directly addresses force and position constraints on motion in manipulation tasks. Additional behaviors with lower priority than the task can be used to ensure the maintenance of kinematic and dynamic constraints, implement posture behavior, or perform reactive obstacle avoidance based on artificial potential fields [36.15]. The control of all of these aspects of manipulation tasks is computationally efficient. As a consequence, the operational space framework is able to maintain these motion constraints while satisfying feedback frequency requirements. However, the operational space framework does not include the consideration of global motion constraints, such as those imposed by the connectivity of the work space. Therefore, the operational space framework is susceptible to local minima, similarly to the artificial potential field method. Such local

minima can occur for all of the aforementioned motion constraints and would prevent the robot from accomplishing its task. To overcome this problem, planning methods have to be applied (Chap. 7 and Sect. 36.3).

The control basis approach [36.16] provides an alternative, compact formalism for combining multiple behaviors. Each individual behavior is described by a controller, represented by a potential function $\phi \in \Phi$, sensors $\sigma \in \Sigma$, and effectors $\tau \in \Upsilon$. A particular controller ϕ can be parameterized with sensors and effectors. A particular instance of a behavior can be written as $\phi|_{\tau}^{\sigma}$. These controllers can be combined using null-space projections, similar to (36.13). In the control basis framework, (36.13) would be written more compactly as

$$\phi_n \triangleleft \cdots \triangleleft \phi_3 \triangleleft \phi_2 \triangleleft \phi_1, \quad (36.18)$$

where we abbreviate $\phi_i|_{\tau_i}^{\sigma_i}$ with ϕ_i . The relation $\phi_i \triangleleft \phi_j$ means that ϕ_i is projected into the null space of ϕ_j . We say that ϕ_i is executed *subject to* ϕ_j . If more than two behaviors are combined, as shown in (36.18), each controller ϕ_i is projected into the combined null space of all superior tasks.

The control basis represents a general framework for combining controllers and is not limited to the notion of task-level control. In addition to the aforementioned formalism for representing combinations of controllers, the control basis also encompasses discrete structures that define transitions between combinations of controllers. Such transitions can be specified by the user or learned with techniques from reinforcement learning [36.16]. The control basis can compose multiple task-level controllers to implement manipulation tasks that cannot be described in terms of a single task-level controller.

36.3 Manipulation Planning

In order to appreciate the computational challenges inherent to gross motion planning for manipulation, it is useful to adopt a mathematical formalism for analysis. The chapter on planning (Chap. 7) introduced the *configuration space* (*C-space*), which represents the space of allowable transformations of the robot. In general, the set of all allowable transformations forms an *n-dimensional manifold*, in which *n* is the total number of degrees of freedom (DOF) of the mechanical system. For a robotic manipulator, the configuration space is defined by its kinematic structure (Chap. 2). One common class of manipulators is *serial-chain* manipulators, which consist of a series of revolute or prismatic joints connected to form a linear kinematic chain. The discussion of manipulation planning in this section focuses on configuration spaces arising from single serial-chain manipulators. However, the mathematical formulation generalizes to more complex robots such as

humanoids (Fig. 36.4; Chap. 67), whose upper body consists of two cooperating manipulator arms attached to a movable base (Chap. 39). The model considered here greatly simplifies the problems of grasping, stability, friction, mechanics, and uncertainties and instead focuses on the geometric aspects. In this section, we will consider a simple example of a manipulation task that involves a classic pick-and-place operation. Section 36.4 further considers grasping and contact states in the context of assembly operations, and Sect. 36.5 gives an overview of techniques to unify feedback control and planning for more complex manipulation tasks.

36.3.1 Configuration Space Formalism

The basic motion planning problem is defined as finding a path in the configuration space connecting a start and a goal configuration while avoiding static obstacles in the environment (Chap. 7). Manipulation planning involves additional complexity because manipulation tasks fundamentally require contact with objects in the environment. When objects are grasped, regasped, and moved, the structure and topology of the free configuration space can change drastically. However, manipulation planning shares the same basic theoretical foundations and computational complexity as classical path planning, such as PSPACE-hardness (Chap. 7).

To be more precise, we will utilize a formalization for manipulation planning that is primarily due to *Alami*

Fig. 36.4 Simulation of the H6 humanoid robot manipulating an object

et al. [36.17], and adapted in *LaValle's* book [36.18]. Our goal is to gain understanding and intuition regarding the search space for manipulation tasks and the different situations that can arise. Throughout this discussion, bear in mind that the geometry and relative positions of the manipulator, the manipulated objects, and the obstacles in the workspace determine both the geometry and topological structure of the free configuration space. Within this framework, manipulation planning can be intuitively placed in the context of planning for *hybrid systems* [36.19]. Hybrid systems involve a mixture of continuous variables and discrete *modes*, whose transitions are defined by switching functions (for a discussion of hybrid systems in a planning context, see Chap. 7 of *LaValle's* book [36.18]). In the case of manipulation planning, the effect of grasping, repositioning, and releasing objects in the environment corresponds to switching between different continuous configuration spaces.

Let us consider a simple example of a simple *pick-and-place manipulation task* that requires a robot manipulator \mathcal{A} to reposition a single movable rigid object (part) \mathcal{P} from its current location in the workspace to some desired goal location. Note that accomplishing the task only requires that the part \mathcal{P} reach the goal location, without regard to precisely *how* the manipulator does so. Because the part cannot move by itself, it must either be transported by the robot or be placed at rest in some stable intermediate configuration. There are some configurations in which the robot is able to grasp and move the part to other locations in the environment. There are also forbidden configurations in which the robot or the part collides with obstacles in the environment. The solution of a manipulation planning problem consists of a sequence of subpaths for the robot moving alone or moving while grasping the part. The primary constraints on the allowable motions are:

1. The robot manipulator must not collide with any obstacles in the environment while reaching for, grasping, or regrasping the part.
2. The robot must adequately grasp the part while transporting it (for details on grasping and metrics for stable grasps see Chap. 38).
3. The robot manipulator and movable part must not collide with any obstacles in the environment while the part is being transported.
4. If the part is not being transported by the robot, it must be placed at rest in some stable intermediate placement.
5. The part must end up at the desired goal location in the workspace.

The two modes of operation give rise to the hybrid systems formulation: either the robot moves alone, or the robot moves while grasping the part. In the literature, motions of the robot holding the object at a fixed grasp are called *transfer paths*, and motions of the robot while the part stays at a stable placement are called *transit paths* [36.17, 20, 21]. Solving a manipulation planning problem involves searching for a connected sequence of *transit* and *transfer* paths for the manipulator that will accomplish the task. For an autonomous robot, the ideal is to utilize planning algorithms that will automatically produce correct sequences of transfer and transit paths separated by grasping and ungrasping operations.

Admissible Configurations

Building on the notation introduced in Chap. 7, we define a robot manipulator \mathcal{A} with n degrees of freedom operating in a Euclidean *world* or *workspace*, $\mathcal{W} = \mathbb{R}^N$, in which $N = 2$ or $N = 3$. Let C^A represent the n -dimensional C -space of \mathcal{A} , and q^A be a configuration. C^A is called the *manipulator configuration space*. Let \mathcal{P} denote a movable part, which is a solid rigid body modeled with geometric primitives. We will assume that \mathcal{P} is allowed to undergo rigid-body transformations. This gives rise to a *part configuration space*, $C^P = SE(2)$ or $C^P = SE(3)$. Let $q^P \in C^P$ denote a part configuration. The area or volume in the workspace occupied by the transformed part model is denoted by $\mathcal{P}(q^P)$.

We define the combined (robot and part) configuration space C as the Cartesian product

$$C = C^A \times C^P,$$

in which each configuration $q \in C$ is of the form $q = (q^A, q^P)$. Note that the set of admissible configurations for manipulation planning purposes is more restrictive than simply C_{free} , the space free of collisions with obstacle regions as defined in Chap. 7. We must incorporate the constraints on the allowable motions by removing inadmissible configurations. Figure 36.5 illustrates examples of some of the important subsets of C for manipulation planning.

We start by removing all configurations that involve collisions with obstacles. Let the subset of configurations in which the manipulator collides with obstacles be given by

$$C_{\text{obs}}^A = \{(q^A, q^P) \in C \mid \mathcal{A}(q^A) \cap \mathcal{O} \neq \emptyset\}.$$

We also want to remove configurations for which the part collides with obstacles. However, we will allow the surface of the part to make contact with obstacle surfaces. This happens for example, when the part is

Fig. 36.5 Examples of the various configuration space subsets defined for manipulation planning

resting on a shelf or table, or when a peg-shaped part is being inserted into a hole. Therefore, let

$$C_{\text{obs}}^P = \{(q^A, q^P) \in C \mid \text{int}(P(q^P)) \cap \mathcal{O} \neq \emptyset\}$$

denote the open set for which \mathcal{O} intersects the interior volume $\text{int}(P(q^P))$ of the part for any configuration q^P . If the interior of the part penetrates \mathcal{O} , then clearly these configurations should be avoided.

We can now define $C \setminus (C_{\text{obs}}^A \cup C_{\text{obs}}^P)$, which is the set of all configurations in which both the robot and the part do not inappropriately collide with \mathcal{O} . Next consider the interaction between \mathcal{A} and \mathcal{P} . The manipulator must be allowed to make contact with the surface of the part, but penetration is once again not allowed. Therefore, let all configurations in which the interior of the part overlaps with the robot geometry be defined as

$$C_{\text{obs}}^{PA} = \{(q^A, q^P) \in C \mid \mathcal{A}(q^A) \cap \text{int}(P(q^P)) \neq \emptyset\}.$$

Finally, we are able to define

$$C_{\text{adm}} = C \setminus (C_{\text{obs}}^A \cup C_{\text{obs}}^P \cup C_{\text{obs}}^{PA}),$$

which represents the set of configurations remaining after subtracting away all unwanted configurations. We call this the set of *admissible configurations*.

Stable and Grasped Configurations

By definition, all configurations in the set C_{adm} are free of penetrative collisions between the robot, the part, and obstacles in the environment. However, many of these configurations define the part as floating in space or on the verge of falling. We now consider two important subsets of C_{adm} that are used in manipulation

planning (Fig. 36.5). Let $C_{\text{stable}}^P \subseteq C^P$ denote the subset of *stable part configurations*, which are configurations at which the part can safely rest without any forces being applied by the manipulator. Examples of stable configurations include the part resting on a table or inserted into a larger assembly of other parts. The criteria for inclusion into the set of stable configurations depends on properties such as the part geometry, friction, mass distribution, and contacts with the environment. Our formalism does not consider these issues directly, but assumes that some method for evaluating the stability of a part configuration is available. Given C_{stable}^P , we define $C_{\text{stable}} \subseteq C_{\text{adm}}$ to be the corresponding stable configurations of the part–robot system

$$C_{\text{stable}} = \{(q^A, q^P) \in C_{\text{adm}} \mid q^P \in C_{\text{stable}}^P\}.$$
